Sir:—At a recent meeting of the Canal Zone Medical Society, I presented a series of six cases showing a luetic sign which I have never seen described. It may be that the tropical sun brings this out more distinctly than is seen in northern climes. These six men were all white foreigners and I selected them because they all had the histories and other stigmata which leave no doubt as to the diagnosis. The faces of all these patients have a muddy expression and on close examination one can see a dirty brown or yellowish pigmentation, irregular in outline, blotchy in character, resembling the pigmentation of chloasma. It is seen particularly on the forehead and temples but also on the cheeks, and does not correspond to the areas of solar tanning where the hat protects. In this country it is so distinctive and characteristic that one can almost pick out the syphilitics in any gathering. It develops as early as the sixth month after the initial lesion, and when the disease is untreated becomes more marked with age.

It is particularly valuable as a diagnostic point in women when no opportunity exists for an examination of the husband without exciting suspicion. On comparing this pigmentation with the corona veneris of text books with its coppery-like stains, we see that the two conditions differ essentially.

One of the patients presented illustrated another point which I have frequently referred to in other diseases, particularly rheumatism and late syphilitic degenerations, namely, that the physiological determination of blood by occupation or otherwise generally determines the seat of the lesion. One of these men early in life lost an eye, and inspection showed that the orbit was not so well developed on that side; the chloasmatic pigmentation, or what I prefer to call it, the "luetic mask," was also less developed on that side than the other.

W. E. Deeks, M.D.,
Chief of Medical Clinic, Ancon Hospital.
Ancon, Canal Zone.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE—SANITARY INSPECTORS IN CONFERENCE—FISH AS FOOD—WAR AGAINST CONSUMPTION—TRAGIC SUICIDE—CEREBROSPINAL MENINGITIS—OBITUARY.

London, September 2, 1910.

The British Association (our chief scientific organization) for the Advancement of Science in all its branches, and of which the Medical Association may be regarded as a daughter, opened its 80th annual meeting at Sheffield on Wednesday, when the president, Professor T. G. Bonney, F.R.S., delivered his address. He is a past-president of the Geological Society and Emeritus Professor of Geology in University College, and his address was devoted to the glacial history of Western Europe, with special reference to the phenomena of the ice age or ages in the British Isles, and the hypotheses which have been put forward in relation thereto. Having discussed these in the interesting and learned way for which he is well known, he confessed he could not declare any one to be satisfactorily established, and added: "I think we shall be wiser in working on in the hope of clearing up some of the perplexities." There are stages, he said, in the development of a scientific idea, when our own best service is "by insisting that the giving of a name cannot convert the imaginary into the real, and remembering that if the hypotheses set on trial are treated as axioms, the result will often bring disaster, like the building a tower on a foundation of sand." I commend this quotation to the attention of the advocates of some medical hypotheses.

There are eleven sections, and some of these unite to consider questions common to them—a plan which supports those who protest against the medical association's divisions as too numerous, when half the number suffice for the whole range of the sciences.

The sections all set to work yesterday with a presidential address in each. Besides these important pronouncements nearly fifty papers were read or taken as read. Moreover, the reports of the numerous committees appointed at last year's meeting were presented to the several sections. Obviously they could not all be discussed, and even those more particularly of interest to your readers can only be considered on a future occasion.

The twenty-fifth annual conference of the Sanitary Inspectors' Association was opened on Monday, and occupied all the week. The report stated that since the last meeting in London there had been a great increase in the membership, and a scheme of examination had been arranged which will come into operation immediately. The meeting was held in the Fishmongers' Hall, kindly lent for the occasion, and the president, Sir J. Crichton Browne, appropriately devoted his address to the importance of fish as food. No city company, he said, had done more important work than the fishmongers, and none did work more interesting to his audience, for it had in reality carried on the work of sanitary inspection for centuries. Last year 946 tons of fish unfit for food had been condemned by the company, and more was probably held back from the market on account of the strict surveillance. Ptomaine poisoning, gastroenteritis and other insidious ailments might be induced by tainted fish. In Billingsgate this danger was prevented, but it was not so easy to follow the fish to the retailer on whose fine marble slabs sunlight, dust and flies did not make for righteousness. In America and New Zealand it

was not exposed in this way. The president next considered the dangers of shellfish drawn from polluted waters, giving proofs from the recorded outbreaks of disease caused in this way. The company and the medical officers of London and other cities had done much to prevent such occurrences, and people might, as a rule, eat their oysters without fear. But only the commission on the feeble-minded could deal with idiots who went about picking up periwinkles, cockles and mussels close to a sewage outfall. We were more indebted to fish than many realized. Our ancestors largely ate molluscs when laying down the keel of the race, as attested by the accumulations of shells known to archeologists as kitchen-middens. The dietetic value of fish was, next to meat supply, protein and fat enough for the body. Dr. R. Hutchinson calculated that an average herring contained 15 grammes of edible protein and 5 to 10 grammes of fat. Dr. Smith estimated that the despised lobster gave the most nutriment for the price of any animal food. An abundant supply of cheap fish would help in the prevention of tuberculosis, develop improvement in the race and provide employment. Hitherto we have depended on the wild life of the sea, but we might very well establish marine stock farms and sanitary science should be called upon to assist in such an enterprise.

Among the papers read was one by Mr. Quinton, chief inspector for Liverpool, who dwelt on overcrowding and unemployment; one by Mr. West on foods, who said the sale of food and drugs act had suppressed most of the grosser forms of adulteration, but still "the heart of man was deceitful above all things and desperately wicked," in proof of which he said flour of poor quality was bleached with nitrous oxide or calcium phosphate and sultana raisins touched up with sulphur to prevent their age being detected. This might be detected by the blue flame when thrown on the fire to amuse at Christmas! Again, rice was polished with talc and a thick mineral rind added to cheese to increase its weight. He had no faith in the branding of goods by foreign governments, but as to this Mr. McPhail strongly opposed him. A paper on town planning was also read. Yesterday Mr. Cameron, New Zealand's government commissioner, discussed the food supply from that country, and effectively criticised the manner in which frozen meat is handled on arrival in this country. I hope his remarks will be taken to heart by those concerned. The medical inspection of school children was also discussed, the president recalling that when he advocated this 30 years ago he was laughed at. Every parent, he thinks, should keep a life-chart of each child showing its growth, ailments and other points as to its health.

The war against consumption is still being vigorously prosecuted. Since the Edinburgh conference a successful tuberculosis exhibition has been held in Newcastle, and others are to take place throughout the autumn to illustrate the cause, propagation, extent and prevention of the disease. They are the work of the National Society for preventing consumption.

On Saturday last a caravan, built and equipped for the Women's Health Association, started from the Botanic Gardens on a mission to women and girls. The intention is to interest them and the people generally, too, in the importance of personal and domestic hygiene. A modern magic lantern and biograph apparatus will no doubt attract the people, and lectures will be given and leaflets distributed.

When the exhibition was at Liverpool, Sir James Barr gave an address in which he said there was no need for more public sanitoria. The results of these institutions had not been commensurate with their expense. What was wanted most of all was homes for advanced cases which would there be well cared for and kept from infecting others. Let them get plenty of sunshine into every nook and corner of their houses and bacilli would not lurk there. They could not spend too much on their children, but should not burden them with useless book education, but have them taught the nobility of work and how to earn their living. Girls to make good wives and happy homes. Boys to develop strength and character and be good citizens. He admired the boy scouts, who were improving both health and character.

An offer of £1,000 has been made for the distribution throughout the country of posters to instruct the public as to the avoidance of infection and assisting the National Associations' crusade.

Another tragic death has occured in our ranks. A doctor, who had served in Africa, India, Egypt, etc., and afterwards practised here, has committed suicide. It appears that an aged patient under his care had died, and some one had asserted his treatment was not proper. This preyed on his mind. An inquest will be held. At that on the patient, who was 82, it was shown by post-mortem examination that he died from diarrhea.

The outbreak of cerebrospinal meningitis is subsiding, but its considerable extent causes anxiety. A severe case was watched in Leicester Hospital. Dr. Farrar from the Local Government Board after consultation with the medical officers concerned has issued a reassuring statement attributing most of the cases to a mild sporadic form.

Dr. Joseph Nelson, ophthalmic and aural surgeon, Belfast, died on Wednesday. He took his M.D. at the Royal University and L. R. C. P. of Ireland in 1863. He had an adventurous life in the Garibaldi Brigade and in India before settling down in Ulster, where he has been a leader for the last quarter of a century. He had been president of the Ulster Medical Society, and he wrote on tobacco amblyopia.

Mr. Henry Collen Ensor, ophthalmic surgeon to Cardiff Infirmary and the Royal Seamen's Hospital at Cardiff, died on August 23, at 51, after an operation for nasal obstruction.

Dr. Ch. A. S. Dalgleish, late surgeon to the Sunderland and Durham Counties' Eye Infirmary, took his M.D. Dur., in 1892, and subsequently held resident appointments at the Radcliffe Infirmary, Oxford and at Leeds and Newcastle.

The sudden death was reported on Wednesday of Dr. J. Brown Sim, for many years a councillor of the City of Nottingham and a prominent politician as well as physician. He graduated at Glasgow, M.B., 1873: M.D., 1876. He contributed on poisoning by strychnia to the *Lancet* and by savine to the *Glasgow Medical Journal*.

Dr. Thos. Soars, who for nearly 30 years had been coroner for Canterbury, died on Wednesday afternoon, age 69. He conducted an inquest on Monday afternoon, but was seized with apoplexy immediately afterwards and did not fully regain consciousness. He was M.D., St. And., 1882 and M.R.C.S., Eng., 1865.

Dr. Surgeon-General John Lister Paul (retired) died on August 25, age 83. He graduated at Edinburgh in 1848 and joined the Indian Medical Service and served until 1877. He has held various appointments, including the Professorship of Surgery at Madras and Surgeon to the General Hospital.

Another Indian Dr. Surgeon-General (retired), Dr. F. M. Skues, died August 13 of cardiac failure, aged 76.

Dr. I. C. Paley, J.P., a retired Surgeon-Major of Militia, has died at the age of 85. He was M.R.C.S., 1846; M.D., St. Andrews, 1873. He had served in both militia and volunteers and on foreign service at Gibraltar, 1855-6. Was a magistrate for Lancashire.

Progress of Medical Science.

New York Medical Journal, September 10, 1910.

Pustular Typhoid Roseola.—Cary Eggleston reports the case of a boy fourteen years of age who was admitted to the hospital a week after the onset of his illness with symptoms that pointed to a mild attack of typhoid fever. Upon the abdomen and lower part of the chest there were 12 to 15 or more "spots." The majority were small, two or three millimeters across, and quite typical of typhoid rose spots. Several were larger and were capped with small vesicles, containing a clear fluid. Two or three were very large, 10 or 12 millimeters in diameter, and deep rose red at the base, which was infiltrated and somewhat elevated, forming a distinct areola about a central yellow pustule. The pustules were tender on pressure and bore no relation to hair follicles. A number more appeared on each of two succeeding days. The vesicles dried up and disappeared four or five days after the rose spots faded. Cultures from the pus developed a pure growth of *Staphylococcus aureus*. The patient suffered a relapse but made a rapid and complete recovery. The writer, after a diligent search of literature, finds that Cabiran reports one case of a varioloform eruption in typhoid fever; Alexander reports one case, and Birnbaum three cases, all of which were mild and the patients recovered. The cases of Birnbaum have features in common with the case reported. They all occurred in children, the cultural findings from the pus were not uniform, and in no case were typhoid bacilli found in the pustules, in each case there was a definite de-

velopment of the pustules from existing rose spots. From the few cases reported it seems possible that the development of pustules is due to a secondary local infection by one or another pyogenic organism and not to a pyogenic action of the typhoid bacillus. Whatever the cause the phenomenon is one of the rarest complications of typhoid fever.

Treatment of Phthisis by Immobilization of Portions of the Trunk.—B. G. R. Williams directs attention to the fact that as tuberculous disease progresses, the chest wall becomes fixed, causing lagging locally over the tuberculous process and later diminished expansion; and it is thus that the part involved fails to be aerated properly and this part of the lung suffers from local asphyxia, giving the bacilli a better hold, and making more rigid those portions of the chest wall immediately external. Taking the pathology of the disease into consideration, the author has devised a treatment based upon principles well known in the mechanics of respiration. During appropriate periods he immobilizes certain portions of the trunk, hoping to effect compensative aeration and pabular nutrition of those portions of the lung involved in the tuberculous process. He endeavors to prove that an increase of local aeration of lung tissue, diseased or normal, is possible; and has collected the opinions of well-known physiologists in regard to compensatory respiration. The author finds adhesive plaster a convenient aid in effecting immobilization and describes some of the methods in which it may be applied. He applies the immobilization during certain hours of the day only, and to facilitate matters he leaves the plasters in position and laces them up during the time when immobilization seems desirable. He emphasizes the value of any apparatus which will limit diaphragmatic descension in any patient suffering from tuberculous involvement of both apices. The practical application of a measure of this kind requires for its success more than ordinary diagnostic ability; each tuberculous chest becomes a study in itself, and until the ordinary physician becomes a keen diagnostician he suggests double strapping of the bases or the abdominal binder during certain hours daily in all suspected incipient cases. The author believes that this method may shorten the period of treatment in certain cases having a fairly good resistant power. Those of the habitus phthisicus can scarcely expect so much from the treatment; influences diminishing the proper amount of tidal air or retarding the circulation cannot be readily overcome by any mechanical treatment. The author urges others to investigate along these lines.

A Study of Functional Exercises in Some Nervous Diseases.—By "functional exercises," William Burdick means the accomplishment of acts that are done by a normal individual in his daily life, and says that these differ somewhat for each individual according to his vocation in life. The exercises that the author uses are based upon Frenkel's, more often modified and simplified than made more complex. In most cases locomotion has been the end desired, but to bring this about has required the learning of details one has probably never considered as entering into walking. The greatest danger in connection with the exercises is that of causing fatigue to the nerves. Successful results depend upon perseverance, intelligence, and the condition of the patient. The theory upon which the author works is that frequently repeated exercises done voluntarily teach the cortex of the brain to control and direct the act. The treatment of twenty cases, which includes seven of tabetic ataxia, three of paralysis agitans, two of combined sclerosis, one of multiple sclerosis, two of hemiplegia, two of anterior poliomyelitis, one of multiple neuritis, one of diffuse degeneration of the spinal cord, and two of spinal lesions undiagnosticated lead the author to conclude as follows: (1) In no case has there been a failure to better the difficulties of movement; even though the betterment might be slight it was such as to make one believe more and more in the possibilities of exercise. (2) Better coordination can be secured. (3) Exercise will, if unable to overcome the effects of the lesion, be able to teach other muscles to do the work vicariously. (4) These exercises apparently retard the progress of the disease.

Journal of the American Medical Association, September 10, 1910.

The Diagnosis of Leprosy.—Isadore Dyer and Ralph Hopkins regard it as highly important that the cardinal symptoms of leprosy should be learned by the officers of the public health so that the importation of leprosy may stop. This does not require any more legislation, but more education of port physicians. The salient points in the diagnosis of leprosy consist in the recognition of the stamp of the disease, which is always suggested by the dusky hue, the swollen skin, the overhanging eyebrows, and the raucous voice. The hands, too, have thinned epidermis and an altered color that is different from that in any other disease. The presence of tubercles in the skin of the face, at the lips, and about the nose, with others in the pendulous parts of the ears, should make a case suspicious. There are only two conditions which at all resemble tuberculous leprosy, iodism and disseminated tuberculosis cutis. The first-named condition is seldom seen in the areas common to leprosy and the nodules of iodism are highly inflammatory and ready to break down. With tuberculosis of the skin, the lesions are numerous, small and deep-seated, under the epidermis as a rule. They seldom assume a reddened hue. Moreover, this condition on the face is unusual and the lesions are apt to occur bilaterally and symmetrically. The writers suggest that physicians should report cases of leprosy occurring under their observation in order that the actual occurrence of the disease in the United States may be studied and statistics derived which may be of value in establishing an institution for the care of leprosy under governmental control and expense.

Significance of Edema of the Soft Palate.—Lewis S. Somers says that edema of the soft palate, and especially of the uvula, while an apparently trivial symptom, may be the expression of a serious affection. The most frequent and trivial type is that caused by excessive use of the voice. It may be associated with general affections, as rheumatism, grip, etc., or with local affections, as peritonsillar abscess. Again, edema may occur as the direct result of traumatism, such as is caused by operations in this region and the application of the cautery to the tonsils; or it may occur in association with ulcerative processes of the mouth and pharynx. In some cases edema is a prodromal symptom of acute articular rheumatism and it is nearly always an accompaniment of faucitis, as erysipelas, or septic infection edema of the uvula is nearly always an accompaniment. As an indication of serious organic changes in the kidneys, edema of the uvula should arouse suspicion, as it may be the only symptom of approaching uremia. Edema of the uvula is rare in acute nephritis, but occurs in cases of scarlet fever, in which the edematous uvula represents both the virulence of the local infection and the subsequent toxic nephritis. Corrosive poisons may produce this edema. The author discusses the question as to why the uvula should present edema in such a number of conditions. Two factors are especially concerned in the mechanism, traumatism and structure of the uvula.

Pathological Relationship of Ulcer and Carcinoma of the Alimentary Canal.—Louis Blanchard Wilson and Byrd Charles Willis make a brief statement of the present views of the relation of chronic irritation to the development of carcinoma in general. The alimentary canal was a difficult field of observation before the period of abdominal surgery. Views of the presurgical period still linger. They offer the following conclusions:

1. The relationship to cancer of simple chronic irritation of the unbroken free surface of the mucosa of the alimentary canal, as indicated by clinical data, is not readily demonstrable pathologically. 2. Scar tissue at the bases of ulcers, obliterations of the lumina of appendices, and diverticula segregate portions of mucous epithelium from the neighboring epithelium and from the lumen of the alimentary canal. 3. These portions of segregated mucous epithelium tend (a) to degenerate from pressure and diminished blood-supply, or (b) to proliferate and infiltrate the surrounding tissues, thus forming cancer. 4. These islands of segregated epithelium probably should be regarded as points of least resistance only, and requiring the presence of other factors for the production of carcinomata.

The Bronchoscopic Treatment of Bronchial Asthma.—Henry Horn briefly reports three cases of bronchial asthma (Notowny's) in which the treatment consisted in swabbing the mucous membrane of the bronchial tubes with a 20 per cent. solution of cocaine, containing a few drops of adrenalin; he also reports two cases (Galebsky's). These five cases were all that he could find in the literature. He reports one of his own cases in detail and offers the following:

Combining and comparing his results with those of Notowny and Galebsky, he thinks that he is justified in drawing the following conclusions: 1. It is possible in a young adult to have an almost complete closure of a main bronchus, due to a tonic cramp. 2. Notowny's conclusion that the theory of bronchial spasm is false is disproved in this case. 3. The complete cures in some cases and the long period of relief in this case seems to indicate

that the treatment of spasmodic asthma by the methods elaborated in this paper is worthy of more extended investigation and should be given a trial when all other methods have proven of no avail. 4. There seems to be no one bronchoscopic picture characteristic for an attack of spasmodic asthma. We may have normal mucous membrane, spasms and contractions of the large and small bronchi, and redness and swelling, alone or combined in the same case. 5. Tuberculosis, heart disease, slightly scoliotic spine, great weakness, and age seem to offer no contraindication to the use of this method.

Agar-Agar in the Treatment of Constipation in Children.—John Lovett Morse concludes that agar-agar is useful in children, as in adults, in the treatment of the type of constipation associated with small, dry stools. It is harmless and in many instances gives most satisfactory results.

Climatic Treatment of Pellagra.—In a preliminary report C. C. Bass states that all writers on pellagra seem to agree that it is a disease of warm countries and of the warm season; that patients with the disease usually improve at once when cold weather sets in, and that many of them never show further evidence of the disease. He has sent five patients to Colorado and two patients to Tennessee and all have been symptomatically relieved. This preliminary report is published in order to suggest the treatment for the benefit of the August and September crop of cases.

The Lancet, September 3, 1910.

A Report on Twenty Cases Treated with Ehrlich's Specific for Syphilis.—J. E. R. McDonagh at the request of Professor Ehrlich used only intramuscular injections, employing doses ranging from 0.3 to 0.6 of a gram of dioxydiamidoarsenobenzol, or Ehrlich-Hata preparation No. 606. The preparation is only stable as a bichloride, and as it must not be injected in the form of a double salt, it is converted into a mono- or a bi-sodium salt by the addition of sodium hydrate just before using. An emulsion is formed which makes it necessary to use a large needle. If the solution is neutralized the pain is greatly lessened. The author describes the method of neutralizing the preparation and the details of making the injections. It seems from the few cases treated that the earlier the syphilis the larger the dose required. If after an injection the rash becomes more profuse, the dose has been too small. It was the general rule for the temperature to rise to 100° F. on the night of the injection, and to become normal after four hours; sometimes the fever persisted to the third day, but only in those cases which had some toxic edema. In only one case was any albumin found after the injection, and in this case it was transient. In almost every case an induration could be felt in both buttocks at the seat of the injection, which is probably due to a fibrosis caused by the caustic action of the sodium hydrate, and it remains for time to tell whether these indurations will disappear. At any rate they produced no discomfort. Beyond the improvement noted with the naked eye, there was an extraordinary change for the better in almost every patient's general condition. They felt better and put on weight; this is a great achievement, since nearly every patient becomes depressed, anemic, and loses weight under mercurial treatment. It seems that the severer the case the quicker the action. A few cases of recurrence of symptoms have occurred and it is an open question whether the injection can be repeated and have the same action or not. The author believes that they are on the right road to find an absolute cure for a disease which is a curse to humanity.

Influence of the New Ehrlich Preparation, Dioxydiamidoarsenabenzol (606), on Recurrent Fever in Rats.—James McIntosh describes his experiments on rats which were undertaken with the idea of investigating the value of this new remedy as a curative agent in an infection provoked by the *Spirochæta obermeiri*. When a rat whose blood contains a considerable number of spirochetes is given a therapeutic dose of dioxydiamidoarsenobenzol, no diminution in the number of parasites is observed until some six hours later. The spirochetes then gradually disappear from the circulation, and in 18 to 24 hours have completely disappeared. In every case treated the same result was observed, whether it was the first, second, or third day of the infection, and in no instance did a relapse occur in any of the treated animals. The preventive action of this agent, like that of most chemical-therapeutic remedies, is slight though it is greater than that of atoxyl in the case of spirollose in fowls. Rats which have received an injection of "606" at the same time as the virus are found to have developed a complete immunity to the disease. Of several rats thus treated only one was found not to have become immune to a reinoculation. The chance of any toxic effects occurring in the employment of a therapeutic dose of "606" is extremely remote as the *dosis maxima bene tolerata* is six times as great as the *dosis curativa*. It may be said that dioxydiamidoarsenobenzol is a specific remedy for European relapsing fever, and no doubt will be equally efficient in other spirochetoses.

The Value of Ossiculectomy in Chronic Middle Ear Suppuration, as a Means of Avoiding the Complete Mastoid Operation.—Hunter F. Tod has performed this operation in over 120 cases; of these he has been able to verify results in a little over 50 cases. A brief summary of these cases shows that in 52 per cent. the ear is now dry and all signs of suppuration have ceased. In 30 per cent. the discharge is mucopurulent in character, and in almost every case is due to infection through the Eustachian tube. In 10 per cent. it is impossible to say whether the mastoid operation will be necessary. On comparing the operation of ossiculectomy with the complete mastoid operation, the following points may be mentioned. In favor of ossiculectomy: 1. The large number of cases which can be cured or in which the mastoid operation may be avoided; 2. The large proportion in which a good result is obtained with regard to the hearing power; 3. The slight inconvenience of the operation to the patient and the short duration of the after-treatment. As against ossiculectomy it has been urged that in many cases the mastoid operation eventually may become necessary, even although an apparent cure or cessation of the discharge may be obtained for a short time after ossiculectomy has been performed; and also that the minor operation does not render the patient completely free from further risk of intracranial complications. With this he does not agree and the cases reported support his contention.

Iso-Hemolysis in Relation to Cancer.—Harold Upcott concludes that it is evident that the possession of isohemolysis is very far from being pathognomonic of cancer. But then very few signs of the disease in its curable stages will bear this interpretation. A reaction which is positive in 50 per cent. of patients with cancer deserves to be weighed in the balance with other facts in the endeavor to arrive at a diagnosis. The only other conditions likely to be confounded with cancer in which hemolysis is frequently met with are tuberculosis and pernicious anemia, especially the former. In such cases, if hemolysis is proved, it is possible that one of the forms of tuberculin reaction would be of value. A negative hemolytic reaction can, of course, carry no weight.

British Medical Journal, September 3, 1910.

The Spread of Cancer Among the Descendants of the Liberated Africans or Creoles of Sierra Leone.—W. Renner has had his attention called to the increasing number of cases of cancer of various organs, especially of the breast, that have come under his observation in recent years, particularly among the descendants of the liberated Africans. An examination of hospital records and of those of medical practitioners would show that within the last forty years cancer has been spreading rapidly among these creoles. While it cannot be positively stated that cancer is absent from among the aborigines, it is certainly extremely rare, and this fact suggests that the adoption by the creoles of the civilized habits of Europeans is responsible for the increase of cancer. It is noticeable that the aborigines eat little meat and, living in the tropics, do not need this article of diet. On the other hand, the creoles have become meat eaters like the Europeans. The teeth of the creoles also show degeneration, which may be attributed to the use of European articles of diet, as saccharines, preserves, and sweets. If this tendency is not checked epithelioma of the tongue is liable to become as common in the course of fifty years as cancer of the breast is at present in this colony. A comparison of the Sierra Leone creoles who have adopted European customs with the Fantis, or natives of the Gold Coast, who have never taken kindly to civilized customs, although they have been in contact with civilization for several centuries, and among whom cancer is rare, offers further argument in favor of the theory that civilization among these peoples is responsible for the increase of the cancer scourge.

One Cause of Cancer as Illustrated by Epithelioma in Kashmir.—Ernest F. Neve states that during twenty-five years, of 4,902 tumors removed by operation in the Kashmir Mission Hospital, not less than 1,720 were malignant and of these 1,189 were epitheliomatous and 848 were on the thighs or abdomen and were due to the irritation of the kangri, a portable fire-basket, carried by the people under their clothes. The disease is twice as common in

men as in women and is extremely rare under the age of forty. The kangri burn cancer is a typical squamous-celled epithelioma. In the early stages the malignancy is slight, too slow to infect glands, and is very amenable to operation. In late cases deep glands are involved, and in many cases, owing to adhesions and brawny infiltration of the skin and cellular tissue it is inoperable. In many cases its origin is in scar tissue. It is demonstrably due to the irritation from the constant application of heat. In this respect it is similar to other epitheliomata resulting from mechanical, chemical, or thermal irritation. The nature of the cause is opposed to a parasitic theory of origin, and favors a trophic theory of cancer.

Gutta-Percha Tissue for Dressing Wounds.—J. R. Rigden Trist has obtained very satisfactory results by means of a gutta-percha dressing and thinks it well suited to the general practitioner. The method that he uses is as follows: (1) Cut off a piece of gutta-percha tissue of the required size and lay it in a tray of spirit. (2) Disinfect the hand, cleanse the wound, put in stitches, and arrest bleeding by presence of a swab wrung out of spirit. (3) Lift the gutta-percha dressing by one corner with forceps, and allow the spirit to drain off. (4) Lay the dressing upon the wound, and apply a pad of wool and bandage. At the beginning of the third day inspect the wound through the gutta-percha dressing and again on the fifth day without removing the gutta-percha if the wound remains clean. The wound need not be disturbed until the eighth or tenth day, when the stitches are removed and a similar dressing applied and kept in place until cicatrization has sufficiently advanced to eliminate the danger of infection.

Recovery from Arylarsonate Poisoning.—R. Lynn Heard announces the recovery of a case of arylarsonate poisoning which he reported in the *Journal* of March 19. Charles Wray, seeing that report, wrote suggesting the administration of large quantities of water daily as well as of electricity to the temples, of a strength sufficient to produce subjective flashes of light. The patient took from 90 to 100 ounces of water daily, and for ten weeks a constant current of from three to ten milliamperes was applied almost daily for from four to six minutes with an electrode on each temple. The current was usually reversed once or twice. The patient's vision has steadily improved and he has gained in weight and is doing very well.

Berliner klinische Wochenschrift, August 20, 1910.

Protective Inoculation Against Cholera.—Aaser of Christiania had his interest in this subject aroused by the Russian epidemic, and as a member of the staff of the Hospital for Epidemic Diseases, made preparations for immunizing as well as other steps in prophylaxis against cholera. As far back as 1908 he had immunized the attendants in the hospital by Haffkine's method. He procured virulent cultures from Berlin and inoculated the 31 attendants of all kinds who came in contact with cholera cases whenever the latter were admitted. Locally edema was produced; inwardly fever, prostration, somnolence, nausea, headache. This picture of toxemia varied within wide limits. The local symptoms came on in about four hours, and disappeared in from one to two days. The general symptoms appeared later and were also of brief duration. The site of injection was the loose cellular tissue beneath the costal arches. Blood tests, made according to several standards, showed that bactericidal immunizing substances were formed in that fluid which behaved also as agglutinins. This bactericidal power lasts for over a year. Repetition of inoculation adds little or nothing to the protection. The cultures, as already stated, were received living and virulent, passed through guinea pigs, and diluted with saline solution to the desired degree; the bacilli were then destroyed, along with any other germ life, by heat, and carbolic acid added as a preservative.

Duodenal Feeding.—Einhorn of New York has thus far employed this new resource in three cases. He first demonstrated it to the staff of the German Hospital, New York, in February of this year, and one of his cases was treated after that period. Such a method is naturally aided by radiography in demonstrating that the feeding tube is actually in the duodenum. The entire apparatus employed is known as the duodenal pump. The thin narrow tube may be retained in the digestive tract for 10 or 12 days without discomfort, and the patient may be nourished in two-hour intervals. The tube is evidently first swallowed by the patient and then allowed to find its own way into the duodenum. Two or three hours may be required for this purpose. The tube is aspirated from time to time and the presence of an alkaline reaction, bile, and pancreatic enzymes gives evidence that it has reached its destination. The food administered consisted of milk, egg in a fluid state, and lactose. The method will prove useful in complete rejection of food by the stomach, with unsatisfactory results from rectal feeding.

Catheter Cystitis (Hemorrhagic) After Operations on the Rectum.—Hadda, assistant of Prof. Gottstein of Breslau, in a brief communication, seeks to place on record the fact that patients subjected to operations on the anus and rectum are more prone than others to catheter cystitis which has a special tendency to assume the hemorrhagic type. This can hardly be an accidental form of postoperative cystitis, but is doubtless *sui generis*, dependent in all probability on thromboses in the region of the veins of the bladder.

Syphilis Transmitted to Guinea Pigs.—Truffi of Prof. Ascoli's laboratory writes briefly on this subject. We read much about rabbit syphilis, but it is not known generally that guinea pigs may be inoculated with the disease. Transmission to the latter is far more uncertain, and the lesions caused (in the scrotum) would hardly have been called specific before the discovery of the spirochete. With increasing development of technique the author has produced much more characteristic lesions; so that the guinea pig's tissues are no less susceptible than those of the rabbit in positive results. At the same time, as already stated, negative results are considerably more frequent. Thus far guinea pigs have been inoculated from rabbit lesions only. It has been impossible to inoculate a rabbit from a guinea pig or one guinea pig from another.

Münchener medizinische Wochenschrift, August 16 *and* 31, 1910.

Oehler's Symptom in Intermittent Limp.—Goldflam refers to a recent article by Erb on this subject, which gives credit to Oehler for the isolation of a new symptom. Many articles on intermittent claudication refer solely to the lower extremity, which is natural if not inevitable as long as the word limp or any of its synonyms is used. In quite recent years a general term dyskinesia intermittens has been made to comprehend both extremities, upper as well as lower. Oehler was apparently the first to describe this condition in the arm (1907), and should have set about to find some diagnostic symptom which would prove the identity of the disease in the two extremities. However, he did no more than mention a sudden pallor and coldness of the hands, which set in when a pavement rammer was lifted and dropped. Hence, the author thinks that Oehler's name should hardly be coupled with the symptom, because he did not extend his research. The article attracted no attention outside of Germany. Oehler even neglected to test sound subjects for the presence or absence of this symptom. Parkes Weber of England (1908) noted the coldness and pallor of the feet in intermittent limp after flexion and extension at the ankle. The author, in a paper published this year, following prolonged research, was able to find the phenomenon in incipient and latent limp, but later he discovered it in healthy subjects and decided that it has an essential physiological basis. A paper by Janowski, as yet unpublished, which is made up of sphygmographic and tonometric studies, will, it is stated, demonstrate the physiological nature of this sudden pallor of the extremities during certain muscular activities.

Nösske's Procedure in Threatened Traumatic Gangrene of the Extremities.—Erkes states that in 1909 Prof. Nösske of Kiel saved the crushed terminal phalanx of a finger by a very simple procedure. The author soon afterward found an opportunity to test it. A laborer had caught the index and middle fingers of the right hand in a machine. The end phalanges of both fingers hung by bridges of skin, all other structures having been divided. The pulp of the fingers was incised to permit the escape of the venous blood. A suction cup was now applied for 15 minutes to the cold, blue, and insensible members: in other words, Bier's hyperemia was applied in a form suited to the occasion. The fingers were then left in their natural position with an aseptic dry dressing. The next day the parts appeared unchanged, and the treatment was repeated. The dressing was removed after four days, when the phalanges were found of normal color and sensitiveness to needle pricks. The dressings were now changed every third day, and the hand bathed in hot water. Six weeks later patient was found to have perfect functional recovery, with anatomical recovery complete save for minimal interference with flexion at the terminal joints.

Apyretic Action of Koch's Original Tuberculin in Tuberculosis.—Engel, a practitioner in Egypt, calls attention to three cases in which this substance unexpectedly caused permanent defervescence in consumptive

patients. The cases are simply given for what they may be worth, and there are no claims made beyond one that there must be specific curative properties in tuberculin which have not yet been reduced to formulæ. As yet we cannot determine in advance to whom, when, and in what dosage the drug should be given. Thus the author in obtaining his results gave high reactive doses, although these are generally regarded as pernicious as far as therapy goes. The defervescence was not due to direct antipyresis, but to the general improvement. The initial dose was not large but the quantities were pushed until the reaction point.

Technique of the Ehrlich-Hata Remedy in Syphilis.—Alt of Uchtspringe, who has shown himself not oversanguine as to certain claims of the enthusiastic partisans of "606," ridicules the recent attempts of those who seek to make the injection less irritating and states that every one of the so-called modifications was tested by Ehrlich himself before putting the remedy into circulation. It must be remembered that Alt was one of the first to use the remedy, and was in Ehrlich's confidence before the "606" was made public. Therefore as far as technique goes he claims that Ehrlich's original acid solution is the best for intramuscular injection. He is also averse to doubling the dose originally fixed by Ehrlich; and otherwise appears to believe that the new remedy is in some danger at the hands of its friends. He thinks it well to combine "606" with mercurials in some cases; and believes that the older Ehrlich remedy, arsenophenylglycin, is of superior value in late syphilis. We have not yet learned just what becomes of the intramuscularly injected arsenobenzol substance. Alt was enabled to show by autopsies that much remains at the site of injection. Hence repetition of injections might lead to cumulative poisoning. Despite increase in dosage the destruction of the spirochetes is not hastened. Alt is in favor of making the first injection intravenous. Then if the disease reappears he would use an intramuscular injection.

Radicular Sciatica.—Stursberg would isolate a form of sciatica under the name of "Wurzelischias." Several distinct localizations appear to give rise to the clinical picture of sciatica. One of these is limited to inflammation or to some other local affection of the nerve roots. The roots involved include in all probability not only those of the sacral medulla, but those of the superposed lumbar cord. Certain authors have separated syphilitic affections of these roots from ordinary sciatica. The author appears to isolate his clinical cases of "Wurzelischias" by the anomalies of sensation referable to the various segmental levels. In certain cases he even believes that the dorsal roots may participate, and illustrates a case in which the 11th and 12th dorsal roots appear to have been involved in a general radicular sciatica extending from the 11th dorsal to the last sacral root. The significance of these localizations from the standpoint of therapy is marked. Lumbar puncture and heat over the loins would be indicated.

Sterilization of Woman by Röntgen-Rays.—Görl has had this subject under advice for four years. In 1906 he treated a hemophilic woman for myomatous uterus. The woman was 40 years old. Therefore there were two fundamental elements present, viz., inoperable tumor and a woman practically at the child-bearing limit. The patient was sterilized by *x*-rays and ceased to menstruate. The myoma slowly resolved. Since that epoch the author has treated eight other women with the aim of sterilization. Two may be eliminated because of faulty attendance, the results being incomplete or doubtful. Two were sterilized in from 15 to 18 exposures, but the age was critical (54 and 55). One woman, aged 42, is still under treatment. The preceding represent the questionable results. Three cases remain which approximate the original in type. The women were relatively young and suffered from conditions which rendered the myomata inoperable. The röntgenization appears to have produced sterilization, but the number of exposures required (85 in one case) was very large. The author is not backward in admitting that some of the general improvement in these cases may have been due to suggestion. The treatment is essentially hemostatic, directed to checking the uterine hemorrhage through action on the ovary and uterus. The myoma need not necessarily undergo involution. The heart (myoma-heart) appears to profit by the treatment. The treatment is harmless to other tissues. The author concludes that the chief indications for röntgen sterilization are menorrhagias which result from disease of the uterus itself (myoma), the heart or kidney, whenever, for any reason, it is inexpedient to do hysterectomy.

Deutsche medizinische Wochenschrift, August 25, 1910.

Relative Resistance to Quinine in the Malaria of Brazil.—Nocht and Werner, army physicians in Brazil, report that in the interior of that country they found cases of malaria in which the parasite was extremely resistant to the action of quinine. More than double doses of the latter failed to prevent the relapses which should be controlled by a course of the alkaloid. The same type of the disease has also resisted other antimalarics, as methylene blue and the Ehrlich-Hata preparation. The latter produced a temporary benefit in the single injection, and one apparent cure, but the authors were evidently loath to push it. The matter is still under consideration. The clinical type of the disease is not peculiar, and the parasite, save perhaps for abnormally small division forms and other irregularities, appeared to be of the typical species.

Disinfection of the Operative Field by Tincture of Iodine.—Müller finds the new method of Grossich far superior to all other methods in disinfecting an operative field. That is to say, he prefers it to soap and water, alcohol, ether, or sublimate. It is not to be used without a full aseptic technique, but is naturally indicated in cases in which the skin over an infected area is itself badly infected, as in an open felon. Cases occur in which the skin to be divided is accidentally the seat of some purulent affection. Further, in traumatisms from machinery and the like it has special advantages. In routine work, when no special urgency exists, the skin is shaved and washed and 10 per cent. tincture of iodine painted on thickly. A second coating is applied 5 or 10 minutes after the first. The operation may be begun 20 minutes after the original application. The tincture should not be allowed to come in contact with prolapsed intestines. In the preliminary washing soap should not be used, the razor being used dry and the water plain. According to Grossich the softening action of soap on the epidermis causes the iodine to sink in too deeply. In other words, the iodine must be applied to the skin when the latter is in a natural state or the seat of an infection. The older remedies all produce specific alterations of the skin in connection with the germicidal action which are more or less disadvantageous. Iodine also produces an effect on the skin, but one which is not a drawback. It is always ready for application, may be applied instantly to the most infected or injured surface, exerts its antiseptic action in a few minutes, and may be depended on. It is especially useful in military surgery. The author admits that it sometimes causes dermatitis and even an outlying affection of the skin of an erysipeloid character, the latter lasting but 12 hours or thereabout. The iodine dermatitis is to be controlled by powdering with zinc oxide. The course of healing is never disturbed by it. Iodine pigmentation is a serious drawback from a cosmetic standpoint. These disadvantages seem to prohibit its routine use in civil practice at least among the well to do, and to a certain extent among women and children.

Alcohol in Hand Disinfection.—Selter believes that alcohol is the ideal and practically a self-sufficient disinfectant for the surgeon's hands. Soap and water are merely accessories, for in macerating the upper layers of the epidermis they merely pave the way for a deeper action of the alcohol. He avoids the use of water altogether by combining 86 parts of alcohol to 14 parts of a hard soap. This forms a firm paste, and if 20 grams of this are rubbed thoroughly into the hands for the space of five minutes we obtain an ideal disinfection. The author's claims are backed up by the usual tables of germ content, the disinfection being estimated in percentages. Thus from 97 per cent. to 99 per cent. of germs were destroyed in their usual lodging places about the nails.

Ulceration of the Frenum Linguæ in Whooping-Cough.—E. Apert mentions a symptom of whooping-cough that he considers almost pathognomonic, and which occurs in about 50 per cent. of the cases observed by him. This is a superficial ulceration of the frenum linguae, generally linear, and which on scraping gives a grayish mass consisting of epithelial cells, and multitudes of leptothrix germs. It is situated in the median line and on the free border of the frenum. Of 252 cases seen by the author, this ulceration occurred in 111; in 105 it occupied the classical point on the frenum. Exceptionally there is the formation of a false membrane. This ulceration appears in the second or third week of the disease, sometimes as late as the seventh or eighth week. Two theories have been given as to its causation: first, that it is due to friction of irregular incisor teeth; second, that it is a specific ulceration. The truth seems to be between the two opinions.—*Le Bulletin Médical.*

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirty-eighth Annual Meeting, Held at Milwaukee, Wisconsin, September 6, 7, 8 and 9, 1910.

THE PRESIDENT, DR. CHARLES O. PROBST OF COLUMBUS, OHIO, IN THE CHAIR.

Report of the Joint Committee on Mailing Infectious Material.—Dr. JOHN F. ANDERSON of Washington, D. C., said that the proposed modifications of the regulations of the mailing of infectious material had finally been promulgated by the postoffice department under date of April 22, 1910. The committee believed that its efforts had resulted in the promulgation of regulations which were a decided improvement over those formerly enforced. The regulations had been considerably simplified. The committee was successful in having the privileges of the mails for the transmission of infectious material extended to include Federal, State, municipal and other laboratories upon the issuance of a formal permit by the Postmaster-General. The report of the committee was accepted, and the committee discharged.

Studies on Self-Purification of Streams.—Dr. G. F. RUEDIGER, Grand Forks, North Dakota, detailed a series of experiments on this subject, and then presented the following conclusions: Colon bacilli and typhoid bacilli disappeared much more rapidly from polluted river water during the summer months than during the winter months when the river was covered with ice and snow. The destruction of these organisms in the river water during the summer months was in a large measure due to the growth of microscopic plants and other organisms which apparently gave off dialyzable substances which were harmful to the *Bacillus coli* and *Bacillus typhosus*. That such substances were given off by the saprophytic bacteria was clearly shown by Frost several years ago, and his experiments simply confirmed Frost's by attacking the problem in a slightly different way. These effects were lost in the winter as no growth took place after 0 °C. The direct rays of the sun also were an important factor and their effects were entirely lost when the river was covered with a thick layer of ice and snow. The practical value of this investigation was very evident. It explained why some of the northern cities where sewage polluted river water was used in the water-works system were more frequently troubled with outbreaks of typhoid fever during the winter months. This was illustrated at Minneapolis last winter, and he believed was true at Lawrence, Mass., before the installation of the filter. When bacteriological analyses of sewage polluted river water were to be made at the site of a proposed water-works intake pipe, it was important that samples should be collected and analyzed both in the winter and in the summer. Analyses of samples collected during the summer did not give reliable information in regard to the condition of that water when the river was covered with ice and snow. The analyses showed that the pathogenic bacteria from the sewage traveled several times as far in the water under the ice, before they were destroyed, as they would in an open river during warm weather.

Dr. H. W. HILL of Minneapolis, Minn., said the experiments which they undertook confirmed in every way the observations and conclusions of the essayist regarding winter river typhoid and summer typhoid. They had found that typhoid bacilli might die out in going down the river in summer under conditions where they would exist during the winter.

Dr. PETER H. BRYCE of Ottawa, Canada, said he noticed in connection with the paper the author seemingly did not take into account the question of sedimentation during the two days in the river. They all remembered Pettenfoker's tests long ago at Munich showed about ninety per cent. of all bacteria in water by dilution and by sedimentation had disappeared within a distance of ten miles.

Dr. E. C. LEVY of Richmond, Virginia, said at the Winnipeg meeting of this association Dr. Freeman and he presented a joint paper on typhoid fever in the South, with special reference to the disease in Richmond. In that paper they brought out the point which had been explained to-day, but made no attempt to explain why it was water-borne typhoid was especially a disease of winter months, but they proved to their satisfaction that such was the case. Their opinion was arrived at purely and simply from an epidemiological standpoint. They had no laboratory facts to corroborate this. During the years since that time their views had been confirmed in every way to such an extent that in Richmond, after they had passed the winter months, they did not worry about water typhoid.

Dr. RUEDIGER stated he should like to say a word with reference to sedimentation, which was referred to by Dr. Bryce. He did not think the factor of sedimentation would alter the experiments in any way; so far as he could see, there would be as much sedimentation in winter as in summer. This factor need not be considered in this particular study. Another study might be based on the factor of sedimentation, which he believed would be the same in summer as in winter.

The Sanitary Registration of Houses in Mexico.—Dr. JESÚS E. MONJARAS of Mexico City said the Board of Health in Mexico had made great progress in the sanitary records in that city. The plan of the city showed the houses in which persons had died of tuberculosis. Each house was shown on the plan by a number which corresponded to the number of cases observed in that house, and each one had its separate file containing all the details of cases as well as the work which had been ordered to improve the sanitary conditions of the houses. With this plan they were able to show the number of deaths caused by tuberculosis or any of its allied affections from the year 1891, with the ages and sex of those who died, and the wards in the City of Mexico in which those deaths were recorded. The sanitary registry of the houses, therefore, constituted a necessary institution in all cities by the aid of which the sanitary and municipal authorities, as well as the general public, could obtain easy and certain knowledge of the houses which constituted foci of infection.

Dr. FREDERICK TORRALBAS of Havana, Cuba, stated the work the essayist had described had been carried on in Havana for some years. It was the duty of the sanitary inspector to cover the complete history of houses. An inspection was made of from 1,800 to 2,000 houses a day, so that cases of tuberculosis were easily traced.

Sanitation of Bakeries and Restaurant Kitchens.—Mr. CHARLES B. BALL of Chicago said that in their experience with bakeries and restaurant kitchens they were led to the conclusion that new installations of restaurant kitchens were required. Ample space must be provided in which the employees might perform the various operations. The contingency of expansion at a future date should be considered, as the tendency to enlarge the dining room, without providing additional kitchen facilities, was found in a great many cases. The arrangement of the various appliances in their relation to each other should insure the isolation of dishwashing and garbage storage from the handling of food. Adequate provision must be made for the removal of cooking odors, not alone from the ranges, but also from vegetable boilers, so as to avoid nuisance in other parts of the building and in the neighborhood. The Underwriters' Association now required that ventilation ducts from large ranges be built of heavy iron plate and carried through the top of the building without any other connections, so that the grease and soot may be burned out

of them as from a chimney flue, without incurring fire danger to other rooms. Ample toilet facilities and washrooms, separate for each sex and apart from those provided for the public, must be furnished. The wash-basins should be located outside of the toilet rooms in order that it might be apparent to those in charge that the hands are cleansed after leaving the toilets. Proper locker rooms, with exceptional means of ventilation, must be provided in order to avoid the nuisance of the storage of either street or working clothes in tightly closed cupboards. Well-ventilated refrigerators were required in numbers sufficient to afford separation for the different classes of food and especially for milk and butter. The best examples of the application of these rules of design to new bakeshops and kitchens were to be found in upper stories, preferably the top story, of certain high buildings. Such installations of superior type were at present by no means rare.

Practical Methods of Supervising the Milk Supply of Cities.—Mr. J. Bosley Thomas of Baltimore discussed permits for the sale of milk and cream; methods of keeping records; collecting samples and recording results; methods of transporting and delivering milk; communicable diseases, diseases in houses where milk was delivered in bottles; bovine tuberculosis; supervision of dairy farms; butter-fats standards, and said that while there were many admirable methods used by various authorities in the administrative control of the milk supply, there was little or no standardization of these methods. It, therefore, seemed advisable that some representative society or body should appoint a committee to establish or recommend standard practical methods that would be capable of universal use.

Saving Children from Milk-Borne Diseases.—Mr. Nathan Straus of New York said that the old city of New York, now the Borough of Manhattan, had established a new record in the saving of the lives of babies. Notwithstanding unusually severe periods of intensely hot weather the past summer, there had been fewer deaths of children under five years than in any preceding summer, and for the first time in the history of the city the summer mortality had fallen to a rate less than 50 per thousand per annum. When he first undertook to protect the babies of New York from milk-borne diseases by supplying pasteurized modified milk in 1892, the summer saw the dying of 6,612 children under five years, making a rate per thousand per annum 136.1. With the steadily increasing use of pasteurized milk there had been a steady decline in infant mortality, until the summer just ended showed only 3,900 deaths in a population of children larger by 125,000 than that of 1892. In other words, in 1892, 064 children out of every 1,000 survived the summer, while in 1910 there were 988 who escaped death out of each thousand. In his practical experience the saving of children from milk-borne diseases warranted the assertion that the pasteurization of milk supplies of our cities, under careful health department supervision, would infalliby reduce the number of cases of infectious diseases and save lives of babies. In no way could this Association save so many mothers from grief and loss of their little ones as by hastening the time when efficient pasteurization would be the rule, and when the milk-borne diseases would be as rare as the plagues that medical science had practically abolished.

At the general meeting of the Association, which was open to the public, addresses of welcome were delivered on behalf of the city of Milwaukee, by Hon. Emil Seidel, Mayor; on behalf of the State of Wisconsin, by Judge William J. Turner, and on behalf of the medical profession, by Dr. W. A. Batchelor.

The responses to these addresses of welcome were made on behalf of the United States by Dr. Richard Lewis, Raleigh, N. C.; on behalf of the Dominion of Canada, by Dr. Frederick Montizambert, Director-General of Public Health, Ottawa, Canada; on behalf of the Republic of Mexico, by Dr. Jesus E. Monjaras, Mexico City, Mexico, and on behalf of the Republic of Cuba, by Dr. Frederic Torralbas, Havana, Cuba.

The Prevention of Mental Defects and Mental Diseases.—Dr. William A. White of Washington, D. C., discussed the preventive principles in the field of mental medicine. The practical things that might be done at once in any community were these: "1. The securing of legislation that places the responsibility for the care of the insane previous to committment in the local health office. 2. Every city of one hundred thousand inhabitants, or over, to have a psychopathic ward connected with its municipal hospital, which is as accessible for the mental case as the other wards are for general medical and surgical cases. This ward should have an out-patient department. 3. The organization of an after-care society to assist persons who have been discharged from a hospital for the insane to get on their feet and to point out to them ways of avoiding the conditions which led to their breakdown. 4. The passage of adequate laws for the control of the labor of women and children. 5. Popular education. By the use of this term I am not merely dealing in a glittering generality that may mean nothing or everything. We have in this country nearly two hundred state hospitals for the care of the insane. These hospitals, each one of them, should be a center of information for the community in which it exists, and its medical officers should use their position to spread information about mental disorders. The superintendent, or a member of the staff, should deliver one or more popular lectures each winter to which the public are invited. Much might be accomplished in this way if all hospitals would do this. 6. Field work from the state hospitals and psychopathic wards as centers to study conditions under which insanity has developed, to furnish assistance to the hospital in dealing with its patients, and to cooperate with the after-care society. 7. More liberal support by city and state of scientific research work in this field, especially along the lines of etiology and prophylaxis.'

The Prevention of Feeblemindedness.—Dr. E. R. Johnstone of Vineland, N. J., stated two or three states had passed laws authorizing the unsexing of certain degenerates after they get in institutions, but please note they had to get in the institution first. He heartily approved of the operation of castration and merely agreed to vasectomy and oophorectomy for want of something better, for after these operations had been performed a fair percentage of the cases might be returned with safety to their homes, and thus make room for others in the institutions, but the ideal way was to gather all of the feebleminded into institutions, and train them in so far as possible to be self-supporting; plenty of industrial occupation and very little academic training. Thirty to fifty per cent. could be made entirely self-supporting after ten years' training. Take the women of childbearing age first and teach them to raise and can small fruits, raise poultry and garden truck, knit underwear, weave rugs, carpets, etc. Then take the others as young as possible and the economic problem came close to solution. He stated they should not talk, but get to work. The numbers were increasing. If they did not care for them in well-conducted training schools where they might learn to contribute toward their own support, they must keep them in almshouses, reformatories, prisons and other institutions, and when they were led into evil ways they had to pay for these patients' arrests, their trial, and the damage they had done. If feeblemindedness was to be checked, they personally must do something.

Preventable Nerosis.—Dr. C. H. Hughes of St. Louis Mo., stated they had heard a great deal of late about the

conservation of forests, which had been a subject of national concern, but what he wished to speak about was the prevention of the neuroses which underlay the physical, the moral and the mental integrity of the people, and which, if not considered and timely regarded, would eventuate in degeneration and degradation of their people, such as have visited the people who had gone before. The neuroses constituted the bane of civilization. It was the neglect to care for a neurosis that caused the greatest of human generals to fall. It was an epileptoid condition, which was neglected, that caused Napoleon Bonaparte to lose the Battle of Waterloo. They were for prevention of the neuroses, those conditions of mind and of the nerve centers otherwise that had so much to do with the individual in the community, with the individual on the firing line in the battle of life, and with the individual who had to meet the duties and obligations of their modern civilization, with its strenuous demands, and it was in the prevention of the neuroses, beginning with the cradle and extending up to manhood and through manhood, they had most to do as physicians, who wished to conserve the vitality of their race and save America. They must take care of the neuroses because they were the bane of civilization; they were the bane of the family life; they were the bane of the social life. The incongruities and unhappiness that existed in families and revealed so largely in the divorce courts were the product on one side or the other, and oftentimes on both, of the dominance of the neuropathic element in one or the other, or both members of the family, and they were called misfits. They were called incompatibilities by lawyers, who could not find a better term, but they were conditions of neurotic ill-adaptability. They were physical misfits. What he meant by the neuroses was not alone functional conditions of the nervous system, because the line of demarcation between functional and organic disease was only a question of time and of study and further observation, but the functional affections of yesterday were the organic troubles of to-day. The time was coming when they would understand hysteria to be an organic disease. Insanity came down to them in its predisposing element in the majority of instances as an inherent predilection, an inherent organic tendency, and superadded to it came the disturbances or influence of environment, the disturbing influences of depressive passion, the influences of conditions of overstrain, overworry, which over-annoy the human mind. They should have a reasonable regard for the powers of the growing child, so that he might not be overstrained. He should have an adequate amount of fresh air, abundant nutrition, ample time for rest, and the prevention of those conditions which came from excesses was the cardinal principle which underlay the prevention and evolution and final destructive development of all neuroses.

Dr. John H. Hurty of Indianapolis said what if they did save a child from diphtheria or scarlet fever and yet failed to save it from some neurosis. The child was lost just the same. The longer he lived and worked in the science of hygiene, the more he was convinced that there was no hope to work with the adult. They must go back and instruct the child. That being done, they had taken the first step. Under their present form of education they did not do that except to a limited degree. The thought was gradually penetrating their minds that the child must have playgrounds and fresh air. They have been shutting out the air from the school room and calling it economy. They had been buying sites for school houses without playgrounds, and calling that economy, and it was the worst kind of extravagance. Something must be done to prevent the building of insane asylums, taxing the people, raising the rates, and having insane on every hand, and the way to do that was to begin with the child.

Dr. Henry A. Norden of Sturgeon Bay, Wisconsin, stated that aside from trying to make a living in the practice of medicine, he had been riding a hobby—the education of children. Neurotic conditions were superinduced by night studies on the part of children. He stated you should not blame the teachers; should not blame the school board, but blame the people who were behind them and have them prevent the school board from doing what they should do. It was absolutely necessary, considering the way education was carried on to-day, for the child to study at night or to sacrifice the playtime of the day. It was almost impossible for children to study in school with one section of the school room reciting. He had suggested frequently in his work to cut down the number of hours of school sessions; that they use the school session for the recitation and explanations, and allow a part of the day to be used for pleasure and part for study. In that way they could prevent neurotic conditions that were produced by night studies.

Dr. E. C. Rogers, of Faribault, Minnesota, stated wherever there was a family with two feebleminded children, that family ought to be studied carefully, its ancestry gone into, and the mental condition of these children studied carefully, and from the work that was now being carried on they hoped to have data which would give them the facts necessary to make statements as to what should be done towards prevention.

President's Address.—Dr. Charles O. Probst of Columbus, Ohio, said that a renaissance in health was at hand. Never before had the public shown such interest and enthusiasm in health measures. Never had it so nearly reached a realization of the immense possibilities in preventing sickness and prolonging life. The time was ripe for cooperation of the widest sort. Without attempting to even outline a plan for cooperation, he recommended that by committee or otherwise the question he investigated of the possibility of uniting or concentrating the efforts of the different national organizations in the four countries represented whose work concerned in any large measure the promotion of the public health. If moral prophylaxis came within the scope of social hygiene, the question of providing suitable amusement for the working people became of greatly increased importance. Especially was this true for working girls. The lack of such places in large cities was among the chief causes of the social diseases. The department of child hygiene of the Russell Sage Foundation, established in 1908, occupied a part of this field. Its purpose in part was to conduct researches and promote activities favorable to the physical, moral, and intellectual welfare of children, especially public recreation, and the health and progress of school children. This Association stood for the highest possible standards in public health. In various ways it had given weighty support to many health movements for improving general health conditions, and notably in the interest of pure food and the establishment of a national health department. The family physician must long remain the chief instructor and most potent factor in preventing the spread of dangerous infectious diseases. The strongest nation, the one of greatest achievements, would in the end be the one that gave the greatest amount of intelligent care to the health of its subjects. Eventually all health interests should be administered by the government. If the first step towards the centralization, or at least the cooperation, of the many associations devoted to health problems could be taken at the meeting, it might be the means of hastening the day when every individual would be given time and opportunity for the pursuit of health and happiness, and the certain knowledge of how and where to find them.

Organization of the Pennsylvania State Department of Health.—Dr. Samuel G. Dixon of Harrisburg,

Pennsylvania, said from July 22, 1907, to June 30, 1910, 32,347 poor tuberculosis sufferers had received the skilled medical aid and the attention of trained nurses which the Department's one hundred and fifteen dispensaries provided. The death rate from tuberculosis in Pennsylvania had fallen from 134 to 120 per one hundred thousand of population in four years. This meant a saving of 1,000 lives annually. From October, 1905, when the State began its free distribution of diphtheria antitoxin among the poor, down to December 3, 1909, 20,794 cases of this dread disease, mostly little children, were treated with the life saving serum. They knew by statistics that without antitoxin 42 out of every 100 of these children would probably have died, but with the aid of the State's antitoxin the death rate among these poor little sufferers was reduced to 8.48. Free antitoxin was also given in 15,125 cases, mostly children, who had been in contact with the disease. All but a very few of these were absolutely protected against diphtheria. A very low estimate of the saving of child life resulting from the state's free distribution of diphtheria antitoxin since 1905 was about 8,000 lives, a pretty good investment of the taxpayers' money. And what of typhoid fever in view of all this work for pure water? In 1906, 56.5 out of every 100,000 people died from this disease; in 1907, 50.3; in 1908, 34.4, and in 1909, 23.9. That is, there were now living 2,363 people who, had the death rate of 1906 prevailed in 1909, would have died from typhoid. In 1906 and 1907, the death rate in Pennsylvania per 1,000 of population was 16.5; in 1908, it dropped to 15.7 and in 1909 to 15.3.

Report of Committee on Education of the Public as to the Communicability and Prevention of Gonorrhea and Syphilis.—This report was presented by the Chairman, Dr. George M. Kober, of Washington, D. C. The report contained several recommendations, which were referred to the Executive Committee for consideration, and which were reported back to the general meeting subsequently in the following amended form. The committee recommended: "1. The recognition, study and control of the prevalence of these, as with all other communicable preventable diseases in order to ascertain the distribution of them. 2. An educational campaign for parents of all social classes and children of all ages and sexes. This teaching should be not only moral, but also medical in the widest sense. (a) Proper distribution of circulars, pamphlets and other literature by state health departments through all suitable channels. (b) State health departments to instruct all its local health officers in sexual matters, and direct them to make a systematic effort to educate the people in their respective communities. (c) State health department to make a definite and determined effort to awaken and interest the medical profession in this fight against veneral diseases. (d) State health departments to send out specially trained paid teachers and lecturers of their own, supported by exhibits and lantern slides to address special meetings of parents, health officers, medical men, teachers and others in schools, colleges, churches, etc., on these and other preventable diseases. (e) State health departments to encourage the organization of local leagues or associations whose purpose shall be the support of and control of a crusade against the spread of all communicable diseases. Said societies to include every profession and walk of life; to depend on philanthropists for necessary funds rather than upon paid subscriptions for financial support. (f) Health departments to interest and provide for the authorities having charge of the educational curriculum in public and private schools. (1) By introduction of biology into the graded courses of all schools. (2) To provide instruction in sexual matters for students of the upper grades. (3) By special instruction to normal school students who are to become the instructors. To impress upon presidents, deans, preceptors and teachers the necessity of exercising their influence on students in reference to the communicability of syphilis and gonorrhea, and to inculcate a morale of protection among the college fraternities. (g) T utilize the public press for the proper occasional presentation of the subject, and to discourage the display of advertising matter which encourages the exposure to dangers in these diseases. (h) To utilize church clubs, fraternal societies, trade unions, women's clubs, and especially mothers' clubs for instruction of parents. (i) Health departments to recommend the enactment of laws for: 1, physical inspection and segregation of prostitutes. 2. Notification and report (by number, if desired)of venereal cases. 3. Physical examination of men before marriage, male applicants for marriage license being required to obtain same to submit to an examination by a duly qualified physician for the purpose of ascertaining whether said applicants are free from venereal diseases. 4. To make it a crime to spread any venereal disease. 5. Keeping open free night dispensaries and maintenance of special dispensaries and hospitals for these diseases. (j) Advocacy of temperance on account of the relationship between alcoholism and venereal diseases. (k) Advocacy of personal cleanliness and venereal prophylaxis. (l) Advocacy of early marriage." These recommendations were adopted.

Venereal Diseases Among Seamen of the Merchant Marine.—Dr. J. W. Kerr of Washington, D. C., stated there were treated 1,281,427 cases of sickness from all causes, or an average of 53,392 patients annually. Of the total number, 106,090 were cases of syphilis in one of the three states, 4,420 being the annual average; 117,336 cases of gonorrhea (including gleet), representing an annual average of 4,889 cases; and 39,819 were cases of chancroid (including ulcer of the genitals), or an average annually of 1,659 cases. The total number of venereal cases treated and classified as above during the period mentioned was 263,245, or an average annually of 10,969 cases. It would thus be seen that these venereal cases represented 20.5 per cent. of the total cases treated. This percentage it would be understood represented cases of syphilis, gonorrhea and chancroid, and did not include complications or sequalæ of those diseases.

Dr. J. R. Kean of Washington, D. C., made a plea for applying the usual methods of preventive medicine to venereal diseases, and, among other things, said: he did not think it was either wise or necessary for scientific men interested in the good of the race and of the country to take any part in the discussion of the relation of this evil to society. It was sufficient for them to know the following facts, that the prostitute was a present confrontation of the problem. There was no reason to think that these diseases were beyond the reach of preventive medicine any more than other contagious diseases, and their immunity from restriction, must be attributed to the public disinclination to discuss them and legislate concerning them. He hoped that this association would not be deterred by the outcry of certain classes of persons who were accustomed to think with their emotions rather than their brains, from taking the bold stand in this matter which was justified by science, by common sense, and by the demands of the public good.

A Consideration of Venereal Prophylaxis in the U. S. Navy for the Benefit of Public Health Officials.—Dr. Charles N. Fiske of Washington, D. C., stated about fifty per cent. of the enlisted personnel of the Navy had a venereal disease during an average of four years. During 1008 there were 4,681 original venereal infections which entailed a loss of service and expense for treatment of 106,526 sick days; there were 1,001 cases of syphilis which represented nearly seven per cent. of the total physical disability of the Navy for that year. While

the morale had steadily and vastly improved during the past ten years in other respects the damage resulting from this class of affection had assumed such proportions four years ago that numerous medical officers no longer felt justified in waiting indefinitely for moral regeneration; they felt that military efficiency demanded activities promising more immediate results; they instituted personal prophylaxis by the use of antiseptic irrigation and inunctions following exposure and upon return to the ship or station. Certain results achieved caused the department nearly two years ago to authorize the extension of this work in connection with the customary educational propaganda, and distribution and confidential circulars throughout the service. Sailors and marines did not contract venereal diseases from the Navy, but from civil communities which were as notoriously indifferent to venereal diseases as they were to typhoid and other widespread infections. Military services had practiced compulsory notification of venereal diseases for years and expect civil authorities to undertake similar measures for control. The source of the Navy's 15,000 first enlisted recruits, and the destination of a similar number of men discharged each year, was the civil population; its statistics would indicate that one youth out of every six in the urban population between the ages of seventeen and twenty-four contracted a venereal infection each year. Venereal diseases had by no means yet been conquered in the Navy, but there was evidence that its ravages were being materially lessened, and that instead of encouraging vice through the hope of immunity, the margin of failure of this prophylaxis was sufficiently wide to deter an increasing proportion of the personnel from sexual indulgence. The desire for clean men on clean ships had been stimulated, and no sense of security had been engendered.

Dr. Gardner T. Swarts of Providence, R. I., stated last year, as President of this Association, he took the liberty of appointing a committee to take up the subject of venereal prophylaxis, with the idea that the people of the country were prepared to receive instruction in these matters. These communicable diseases were preventable and if boards of health were to conserve the public health, then these diseases should be put on the reportable list and steps taken to prevent their prevalence as far as possible.

Dr. J. S. Neff of Philadelphia stated he did not think it was possible to compel physicians to reveal the existence of these diseases among their patients, and they would not report this class of cases to health departments.

Dr. John N. Hurty of Indianapolis, Indiana, stated he believed that the road leading to the prevention of venereal diseases was the longest and roughest which hygiene and sanitary science had to travel. At this time, every tribe, every nation, and people of the earth were thoroughly syphilized. Think of that, and now we were proposing to eradicate it. The first man to propose education to eradicate these diseases was Solomon, and he began five thousand years ago, and with education, such as he gave, and such as they proposed to give, these diseases had increased and multiplied. Until they put aside that prudery which now prevented them from attacking this problem correctly, and which prevented them from teaching the child about his sexual nature and procreation, they could make no progress. Let them begin with the child.

Colonel Theodore Roosevelt said that, like any other man in public affairs, he was awake to the needs of the public health. It was necessary to join efforts for the preservation of the public health. It was important not only to keep the health of the individual, but also to keep the health of the nation. Yellow fever was a distinctive national problem. Several nationalities in the western hemisphere had dealt with it and must deal with effectively to prevent the ravages of this scourge. The question of dealing with the public health was a matter of the last two generations. One half a century ago comparatively nothing was known of diseases which were a scourge to the human race. About six hundred years ago the black death desolated Europe, a disease which undoubtedly they could deal with now. Then it took off two-thirds of the population of Europe. He had just come from a trip to the middle of Africa, where disease ravaged mankind as it did their ancestors. He passed through regions where the sleeping sickness had to its credit over 200,000 deaths in one neighborhood. The advances made in the medical profession during the last half century were incalculable. The work of the Isthmus of Panama could not have been done in its present shape a decade ago. They could not have grappled with disease as now. The prime requisite in every nation was to have every man and woman an effective unit. They were dealing with the basic problem of citizenship. Men could not be good unless they were healthy. He welcomed the delegates to this convention who came from foreign countries, especially from the Americas. In the two Americas they were solving the problem of living peacefully together Their only rivalry, far different from Europe, was the endeavor to see which was best able to cope with the problems that confronted them all. He welcomed them as their rivals, who were doing all in their power to uplift and care for the physical well-being of the human race.

Executivve Methods in Preventive Medicine.—Dr. Henry B. Hemenway of Evanston, Illinois, stated health administration was formerly local in nature. The science of public health had now advanced far beyond administration, especially in this country. The American law required a separation of the three branches of government. Health administrators, being of the executive branch, had no legislative power. They might not, however, issue any orders, or regulations except as distinctly provided in the laws under which they were acting. All health authority was derived from the police power of the state. Police power was a system of precaution for the prevention of crimes and calamities. It was a necessary but also a dangerous power; and because of the danger to individual liberty, the courts were inclined to scrutinize its operations closely to prevent abuse. The police of public health started from the idea of nuisance, and presupposed legislative determination in great detail. Even though administered by municipal officers, public health work was essentially state in nature; and in the absence of special constitutional provisions to the contrary, the state had the right to appoint and regulate the acts of municipal health officers. The protection of the state against damage suits was extended to all health officials, so long as they acted within the law, even though error had been committed, and damage resulted to individuals. As compared with other countries, American state executives were ill organized and weak; and one of the weaknesses was shown in the tendency to the appointment of boards, often serving without pay. Since executives had no legislative power, an executive board lacked in responsibility, decision, activity and despatch, without compensatory advantage. There was no more reason why a physician should donate his public health service than that a lawyer should serve without pay as a judge or a banker should give the use of the money needed for public improvements. Health laws should be enacted by the state legislature. The entire health administration of a state should be recognized as one body, having a single head to whom all local and district officials were responsible. Every man should be held responsible for a definite portion of the work. Executive duties were either ministerial or discretionary. If ministerial, the officer might

only do that which was required. If discretionary, he might do anything within that discretion; but neither his acts nor legislation for his guidance might be arbitrary or unreasonable. If the officer acted beyond the provision of the law, he might be sued as a private wrongdoer. Health legislation should be definite, not in general terms, to best safeguard individual liberty. Matters of technical detail in the work of the office might be largely left to subordinates; but the executive must personally and frequently decide upon questions of administration. Such knowledge of administrative law as would give confidence in execution, celerity of decision and definiteness of effort would increase effectiveness. In other words, the head of the department should be a professional administrator with a broad knowledge of sanitary science, not merely a sanitarian or a party politician. At least once a year there should be a conference of state and district officers, at which proposed legislation might be discussed and prepared for presentation to the legislature for enactment.

Dr. C. A. Harper of Madison, Wisconsin, discussed the relation between state and municipal boards of health, saying the interchange of ideas, and the knowledge required by each health officer in knowing how other health officers did their work and met certain emergencies, fully justified the labor and expense incident to holding state or district conferences. If the health officer expected to impart knowledge to others, he must know his subject thoroughly and realize the important role which sanitation and public hygiene play in the prevention of diseases.

Professor E. H. Bailey of North Dakota spoke of the advantages of cooperation between the state board of health and state universities.

Dr. Gustav F. Ruediger of Grand Forks, North Dakota, spoke of the relation of the State University of North Dakota to the State Board of Health, and favored placing the state board of health laboratory under the control and regulation of the state university, under the direction of the professor of bacteriology and pathology.

Dr. Charles A. Hodgetts of Ottawa, Canada, pointed out the functions of the Canadian Commission of Conservation and Public Health.

Dr. H. W. Hill of Minneapolis, Minnesota, spoke of the relations of universities to public health work.

Mayor Seidel of Milwaukee, Wisconsin, discussed social economics and public health. He said that land had a value. Timber had a value, and so had water and mineral deposits. These, with machinery, were important factors in wealth production. But the most important factor of all in wealth production was human labor. Without labor of hand and labor of brain applied to raw material, there was no civilization thinkable. The greatest of all natural resources was human life with its accompaniment of labor. It was good and excellent work to conserve land and timber and water utilities, but it was far more important and far more fundamental to conserve human life and make it more efficient and give it added ability and power to create.

Mr. Frederick Almy of Buffalo, New York, spoke of the inter-relation of national organizations working in the interest of health.

Dr. Frederick Montizambert, Director-General of Public Health, Canada, said the administration of the subject of public health in that country was joint between the Dominion and the Provinces. The administration of the subject of quarantine pertained solely to the Dominion Government, including the inspection and treatment of passengers, crews and vessels from abroad, arriving at the different seaports on the Atlantic and Pacific coasts, and of the persons and trains entering Canada over the international frontier. Leprosy was dealt with by the federal government. The adulteration of foods and drugs was dealt with by the Department of Inland Revenue. Infectious and other diseases occurring within the Dominion were under the administration of the provincial and municipal authorities.

The Mexican Republic Free from Yellow Fever.—Dr. E. Liceaga of Mexico City contributed a paper in which he stated that from the twentieth of December of last year not a single case of yellow fever had been observed either there or in any other part of the Mexican Republic. In spite of the success obtained, the sanitary service continued its action with the same regularity as in previous years, although it was not directing its energies especially against malaria.

Quarantine or Isolation in Diphtheria.—Dr. James Roberts of Hamilton, Ontario, stated in this paper he first established the fact of the dominance of the personal contact factor in the spread of this disease. Defective drains, bad ventilation, etc., although prejudicial to health, cannot cause diphtheria, which was due to the presence of certain bacteria. Overcrowding assisted the spread of diphtheria. Forty-five per cent. of his cases, representing not more than one-quarter of the school population, came from the districts where the industrial classes were centered. The presence of an ignorant foreign element hindered the work of sanitation and favored the spread of disease. Diphtheria, owing to the manner by which it was spread, was a school disease. The Boston Board of Health, after an exhaustive investigation, concluded that it would be impracticable to isolate bacillus carriers who did not themselves suffer from the disease, as they constituted one per cent. of all healthy school children, and these germs were ordinarily of little virulence. The restriction of this disease was for practical purposes limited to isolation of clinical cases and control of the contacts in connection with these. Where isolation could not be strictly carried out at home, hospitalization was the best method. But isolation hospitals were very unpopular, owing to their usually poor equipment, the danger of cross infection, etc. They safeguarded the community, but often at the expense of the individual. Our present-day conception of diphtheria as preeminently a school disease made it imperative that the inspection of school children should be thorough enough for the detection of early cases, and of those children harboring virulent bacilli. When this had been accomplished, regulations intelligently enforced, providing for the proper isolation of all cases either at home or in suitable institutions, would be productive of better results and much less annoyance and hardship than the continued enforcement of antiquated laws and regulations incompatible with their present knowledge of diphtheria.

A Study of the Ventilation of Sleeping Cars.—Dr. T. R. Crowder of Chicago, Illinois, stated the only available method of accurately estimating the air supply of running cars was by determining the amount of carbonic acid gas which their atmosphere contained, and from this computing the amount of air which entered. The problem was mathematically simple, and rested upon the known amount of carbonic acid thrown off by the respiration. This method had been applied in the study of sleeping-car ventilation. Some 2,000 samples of air had been analyzed from these cars. It showed that an average of approximately 40,000 cubic feet of air was supplied hourly to the main sleeping compartment of standard cars, which were equipped with the ventilating system now in common use by the Pullman Company, and that the amount was rarely, if ever, under 20,000 cubic feet. There were rarely more than twenty people in a sleeping car; hence each person was supplied with some 2,000 cubic feet of air each hour. This applied to the findings in occupied berths, both lower and upper, as well as to the car in which the berths were not made up. The high

wind pressure to which running railway cars were subjected resulted in fair ventilation even when they had no special ventilating devices. The amount of air which they received would vary from 15,000 to 50,000 cubic feet per hour, depending upon various conditions. When cars were uncomfortable and felt "stuffy" the fault was not generally to be laid to an inefficient air supply, as was commonly supposed. It rarely happened that the air supply was so inadequate as to bring about this condition, though it might at times contribute to it. The fault generally lay chiefly in an improper control and regulation of the heat supply. The degree of humidity of the atmosphere was also a very important factor; but its control was difficult, and often impossible. In the opinion of the author, heat control was a more important problem in maintaining comfort in sleeping cars than was the furnishing of a great air supply, and relatively greater attention should be concentrated upon this element of the problem and maintaining a hygienic atmosphere in cars.

Dr. JOHN A. AMYOT of Toronto, Canada, discussed the laboratory in its relation to public health, while Dr. William A. Evans of Chicago spoke of efficiency and economy in municipal health work.

The Association endorsed the principles embodied in the Senator Owen Bill for the establishment of a National Department of Health.

A resolution was adopted recommending that a committee (of which Dr. Probst shall be chairman) be appointed to consider and report next year a scheme for instruction in hygiene and sanitation in high schools, and in colleges and universities, with the view to bringing the necessity for such instruction with definite recommendations to the attention of educational authorities.

A new section to be known as the "Section on Sociology" was formed; also one to be known as the "Section on Sanitary Engineering." The following resolution was adopted: WHEREAS, A considerable number of municipal health officers believe terminal disinfection at the conclusion of communicable diseases is of questionable value and extravagant in practice; and, WHEREAS, A few municipal health officers of sound judgment and highest attainment have abandoned this practice as a prophylactic measure; therefore, be it *Resolved*, That the Municipal Health Officers Section refer to the Executive Committee a recommendation that the American Public Health Association appoint a committee to study the end results and practice in communities where terminal disinfection is no longer practiced at the conclusion of cases of communicable diseases.

The following resolutions were likewise adopted: *Resolved*, That this Association appoint a committee to cooperate with the Census Bureau in establishing standard methods of accounting for municipal sanitation. *Resolved*, That this Association offers and accords its hearty approval and commendation of the educational work carried on by the *Ladies' Home Journal* regarding the necessity and ways of teaching children the truth about reproduction and the sexual life.

Officers.—The following officers were elected: *President*, Dr. Robert M. Simpson, Winnipeg, Manitoba; *First Vice-President*, Dr. Fernando Lopez, Mexico City; *Second Vice-President*, Dr. John F. Anderson, Washington, D. C.; *Third Vice-President*, Dr. B. A. Bading, Milwaukee, Wis.; *Secretary*, Dr. William C. Woodward, Washington, D. C.; *Treasurer*, Dr. Frank W. Wright, New Haven, Conn.

LABORATORY SECTION.—*Chairman*, Dr. J. F. Amyot, Toronto, Canada; *Vice-Chairman*, Dr. John F. Anderson, Washington, D. C.; *Secretary*, Mr. B. R. Rickards, Columbus, Ohio; *Recorder*, Dr. H. D. Pease, New York City.

VITAL STATISTICS SECTION.—*Chairman*, Dr. Wilmer R. Batt, Harrisburg, Pa.; *Vice-Chairman*, Dr. C. V. Chapin, Providence, R. I.; *Secretary*, Dr. F. L. Watkins, Columbus, Ohio.

MUNICIPAL HEALTH OFFICERS' SECTION.—*Chairman*, Dr. A. J. Douglass, Winnipeg, Manitoba; *Vice-Chairman*, Dr. Frederic Torralbas, Havana, Cuba: *Secretary*, Dr. E. C. Levy, Richmond, Virvinia.

Havana, Cuba, was selected as the place for holding the next annual meeting.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS

San Francisco, April, 1910.

ANATOMY.

Answer Ten Questions Only.

1. Trace cerebrospinal fluid from the lateral ventricles to the spinal canal.
2. Describe the rami communicantes.
3. Name the bones of the tarsus; use diagram.
4. Indicate, on the diagram, the points of exit from the pelvis of the following nerves; external cutaneous, anterior crural, genitocrural, obturator, sciatic, pudic, superior gluteal.
5. Indicate, on the diagram, the course of the common, internal, and external iliac arteries.
6. What veins are without valves?
7. What cranial nerves are distributed to muscles only, *i.e.* are motor?
8. Give topographical outline of the lungs and bronchi on the anterior chest wall; use the diagram.
9. Give origin and course of the eleventh cranial nerve as far as its exit from the skull.
10. What are the characteristics of arthrodial joints? Give five examples of this class of joints.
11. What is the ischiorectal fossa, how bounded, and what does it contain?
12. When the arm is hanging with palm forward, what bony prominences at shoulder, elbow, and wrist are normally in line?

HISTOLOGY.

Answer Eight Written Questions and Identify Slides.

1. (*a*) Name the structures found in red bone marrow. (*b*) give the function of red bone marrow.
2. Draw diagram illustrating long tissue, naming different structures.
3. Explain the difference between the mucosa of the endometrium and that of the vaginal portion of the cervix. Also make drawing.
4. Give structure of the tonsil.
5. From which germ layers are the following derived? Pancreas, spleen, large intestine, salivary glands, fat.
6. Draw a transverse section of the brain, at a point just anterior to the pons varolii. Name most important parts.
7. Draw diagram illustrating a cell and name all the necessary constituents.
8. Describe the structure of the liver.
9. Explain the difference between the white and gray matter of the brain.
10. What are terminal arteries? Name organs which are so supplied.
11. Identify slides.
12. Identify slides.

PHYSIOLOGY.

Answer Ten Questions Only.

1. How and where is lymph formed?
2. Discuss sleep and its causation.
3. Discuss briefly the influence of the nervous system on the digestive secretions.
4. Describe the movements of the intestines during digestion.
5. Explain the effect of (*a*) expiration on the volume of the brain, (*b*) inspiration.
6. Discuss the formation, function, and fate of glycogen.
7. What is the physiological difference between the brain of man and that of lower animals?
8. Under what circumstances may functional union be made between fibers of different nerve trunks? What practical value has this operation?
9. Give nerve supply and action of muscles concerned in the movements of the eyeball.

10. Do we determine the function of a nerve by the location or function of the center from which it comes or by its peripheral connections? Give your reasons.
11. What is the effect of a destructive lesion in the posterior limb of the internal capsule?
12. To what extent is the secretion of sweat under (*a*) nervous control; (*b*) vascular control?

BACTERIOLOGY.

Answer Eight Questions Only.

1. What are the differences in structure, methods of multiplication sporulation, etc., between the blastomycetes or yeasts and bacteria?
2. What changes are produced on the culture media when *Bacillus Coli Communis* is grown: (*a*) upon gelatin, (*b*) in milk, (*c*) in dextrose, (*d*) in lactose?
3. Describe the conditions necessary to successfully grow *Bacillus tetani* and the appearance of a stab culture in agar or gelatin about the sixth day.
4. What is the difference between an antitoxin and a bacterial vaccine?
5. Name four (4) pathogenic anerobic bacteria.
6. Differentiate between bacillus tuberculosis and bacillus lepræ, taking into consideration staining, culture peculiarities, effect on tissues, and relation to tissue cells of the host.
7. Describe briefly how you would make gelatin plate cultures, using material from a furuncle as the source from which to obtain the germ.
8. Name ten (10) pathogenic bacteria that are Gram positive.
9. What do you understand by the opsonic index?
10. How would you sterilize: (*a*) a culture tube of gelatin, (*b*) a glass container with rubber stopper, (*c*) a platinum needle in a glass handle?
11. Identification of cultures.
12. Identification of slides.

CHEMISTRY.

(*Answer ten questions only.*)

1. What is the poison in most headache powders? Its effect? Antidote.
2. Mention six elementary substances commonly used in their pure state in medicine.
3. What does the presence of an abnormal quantity of chlorine in drinking water indicate?
4. How would you detect the presence of bile in the urine? Give two tests.
5. Give the reaction, specific gravity, and percentage of fats in normal cow's and woman's milk.
6. Mention a secretion in the body that contains cholesterin; one that contains pepsin, and one that contains trypsin.
7. What antidotes should be used in phosphorus poisoning? Explain the action of each.
8. Define and illustrate (*a*) capillary attraction, (*b*) absorption, (*c*) diffusion, (*d*) osmosis, (*e*) endosmosis.
9. In what principal form is nitrogen eliminated from the body? Give the chemical properties of nitrogen.
10. What is the chemical composition of the various renal calculi?
11. Mention one chemical antidote for each of the following: (*a*) Phenol, (*b*) arsenious oxide, (*c*) sulphuric acid, (*d*) mercuric chloride, (*e*) oxalic acid.
12. What are the distinguishing characteristics of urates and uric acid as found in the urine? Give test for uric acid.

GENERAL DIAGNOSIS.

(*Answer ten questions only.*)

1. Give the physical signs of a pleurisy with effusion
2. Give the symptoms of bubonic plague.
3. Give the symptoms and physical signs of aortic insufficiency in the stage of failing compensation.
4. Give varieties, etiology, and symptoms of chorea.
5. Give the symptoms of tabes dorsalis.
6. Describe a Colles' fracture.
7. Give the points upon which you would make a diagnosis of cancer of the stomach.
8. Describe diabetes mellitus, and differentiate it from diabetes insipidus.
9. Differentiate rubeola from scarlet fever.
10. Describe the secondary lesions of syphilis.
11. Give the symptoms of a transverse myelitis.
12. Give the symptoms of cholelithiasis.

PATHOLOGY.

Answer eight of the written questions and identify four slides.)

1. Describe the difference in the pathological changes which take place in degeneration of the tissues and those which take place in atrophy.
2. Give the pathology of tabes dorsalis.
3. Describe the gross and microscopic changes which take place in the spleen, liver, and kidneys as a result of prolonged exposure to malarial infection.
4. What are the postmortem changes usually found in diabetes mellitus in (*a*) children, (*b*) adults of middle age, (*c*) adults of advanced age?
5. What is the average blood pressure in adults fifty to sixty years of age measured in millimeters of mercury? Describe the results if this pressure is exceeded for a considerable time.
6. In bony tissue what variety of malignant growths usually occur, and why?
7. Under what conditions is cerebral embolism most likely to occur? What blood-vessels are most likely to be affected, and why?
8. Describe the local lesion caused by infection by anthrax bacilli; the general or systemic effects, and state how infection usually occurs.
9. Describe the condition present in acute dilatation of the heart. Give the immediate and predisposing causes and the usual final result.
10. State fully why urinary bladder disorders are so frequent and so resistant to treatment in both elderly men and elderly women.
11. Identify two slides.
12. Identify two slides.

OBSTETRICS.

(*Answer ten questions only.*)

1. What zymotic diseases are liable to affect the pregnant and puerperal woman, and how?
2. How soon after the completion of the second stage of labor should the umbilical cord be ligated? How dressed? What are the dangers of improper dressing?
3. What injuries are liable to occur to the birth canal during labor?
4. Under what circumstances are anesthetics indicated in labor? What are the dangers?
5. What are the causes of premature rupture of the membranes? How does it influence the progress of labor?
6. How would you determine if a child is premature at birth?
7. Differentiate between retained and adherent placenta; the management of each.
8. What can be determined by external palpitation of the pregnant woman at the eighth month? How should it be performed?
9. What are the so-called false pains of labor? Differentiate from true pains.
10. Rupture of the uterus; etiology and symptoms.
11. Give the physiology of menstruation; of ovulation: relation, if any.
12. What is inversion of the uterus? Diagnosis and management.

GYNECOLOGY.

(*Answer ten questions only.*)

1. Give the conditions justifying operative measures in fixed retrodisplacement of the uterus.
2. Describe a pelvic hematocele, and give the usual cause.
3. What is the pathology of pelvic cellulitis, and what are the physical signs?
4. Name the most important causes of sterility.
5. Differentiate between a pudendal hernia and pudendal hematocele.
6. What do you understand by the operation for perineorrhaphy?
7. Give the etiology and pathology of chronic endocervicitis?
8. Describe a case of carcinoma uteri, and give some of the most prominent physical signs.
9. Discuss the matter of relative prognosis of cancer of the body of the uterus and cancer of the cervix.
10. Describe the mode of use and purpose of a vaginal tampon.
11. Differentiate between herpes of the vulva and chancre.
12. Name the muscles of the perineum, and give the functions of the perineal body.

HYGIENE.

(*Answer ten questions only.*)

1. Describe in detail the method of transmission of yellow fever.
2. What measures would you adopt to prevent the spread of typhoid fever during an epidemic?

3. What is a septic tank? Describe construction and explain how it acts.

4 What sanitary measures should be adopted in caring for tuberculous patients?

5 Name five of the most common intestinal parasites, and give a short description of each.

6. Give three ways of fumigating a room with formalin; also two methods with other disinfectants.

7. What effect have venereal diseases on the propagation of the human species? Explain.

8. How does the hookworm usually enter the human body? What means would you adopt to prevent its spread?

9. Describe the technique of vaccination, and give the course of a successful case.

10. What is the period of incubation of the following diseases: Plague, smallpox, diphtheria, scarlatina, measles?

11. What is the object of placing traps on all waste pipes? What danger to health would arise if there were no traps?

12. Describe two types of water filter. What should be accomplished by a good filter?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF MEDICAL EXAMINERS.

San Francisco, April, 1910.

ANATOMY.

1. The cerebrospinal fluid passes from the lateral ventricles through the foramen of Monro into the third ventricle; then through the aqueduct of Sylvius (or iter a tertio ad quartum ventriculum) into the fourth ventricle, through the latter, and into the central canal of the spinal cord.

2. See Cunningham's "Anatomy" (1909), pages 615, 616, and 609; or Gray's "Anatomy" (1908), pages 1078 and 1079.

3. The *bones of the tarsus* are: Calcaneus, astragalus, cuboid, scaphoid, internal cuneiform, middle cuneiform, and external cuneiform. For diagram, see Cunningham's "Anatomy" (1909), page 239; or Gray's "Anatomy" (1908), page 242.

4. See Cunningham's "Anatomy" (1909), page 641; or Gray's "Anatomy" (1908), pages 1017 and 1029.

5. See Cunningham's "Anatomy" (1909), pages 840 and 857; or Gray's "Anatomy" (1908), pages 671 and 686.

6. The *veins without valves* are: The venæ cavæ, hepatic veins, portal vein and its branches, renal, uterine, ovarian, pulmonary, cerebral, spinal, and umbilical veins. The sinuses of the skull and very small veins are also without valves.

7. The *cranial nerves exclusively motor* are: Oculomotor (3); Trochlear (4); Abducens (6); Facial (7); Spinal accessory (11); and Hypoglossal (12).

8. See Cunningham's "Anatomy" (1909), page 1257.

9. See Cunningham's "Anatomy" (1909), page 695; or Gray's "Anatomy" (1908), page 1073.

10. See Cunningham's "Anatomy" (1909), page 257; or Gray's "Anatomy" (1908), page 268.

11. See Cunningham's "Anatomy" (1909), page 1281; or Gray's "Anatomy" (1908), page 1548.

12. When the arm is hanging with palm forward the acromion process of the shoulder, the external condyle of the humerus, and the styloid process of the radius are normally in line.

HISTOLOGY.

1. (*a*) See Cunningham's "Anatomy" (1909), page 71; or Gray's "Anatomy" (1908), page 36. (*b*) The *function of red bone marrow* is to form red blood corpuscles; also to help in the formation of bone.

2. See Cunningham's "Anatomy" (1909), page 900; or Gray's "Anatomy" (1908), page 1403.

3. See Cunningham's "Anatomy" (1909), page 1191; or Gray's "Anatomy" (1908), page 1504.

4. See Cunningham's "Anatomy" (1909), page 1035; or Gray's "Anatomy" (1908), page 1223.

5. *Pancreas* is derived from entoderm; *spleen,* from mesoderm; *Large intestine,* from entoderm; *Salivary glands,* from ectoderm; *Fat,* from mesoderm.

7. See Cunningham's "Anatomy" (1909), page 8.

8. See Cunningham's "Anatomy" (1909) page 1121; or Gray's "Anatomy" (1908), page 1345.

9. See Cunningham's "Anatomy" (1909), page 443; or Gray's "Anatomy" (1908), page 833.

10. *Terminal arteries* are such as do not anastomose with other arteries, either directly or by branches. *Organs supplied with terminal arteries:* Retina, brain, kidneys, spleen, lungs.

PHYSIOLOGY.

1. There are two theories as to the formation of lymph: (*1*) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (*2*) That in addition to these the endothelial cells of the capillaries exercise some influence.

2. Sleep is a condition of partial or complete unconsciousness, during which the brain and body can recuperate. Metabolism in general is diminished, anabolism is (relatively) in excess of katabolism. During sleep the respirations are slower and deeper, most of the secretions are diminished, the pulse is slower, the eyeballs roll inward and upward, and oxidation in the tissues is decreased. The cause of sleep is not known. Bradbury (in Allbutt's "System of Medicine") gives the following as hypotheses as to the causation of sleep: (1) Cerebral anemia; (2) chemical changes in the brain cells or neurons, such as an exhaustion of their intramolecular oxygen, or an accumulation of fatigue products; (3) contraction of the dendritic processes and a consequent break in the transmission of nerve impulses; (4) expansion of the neuroglial cell processes, insulating the nerve processes and producing the same effect; (5) loss of consciousness apart from any physical or chemical change; (6) the most probable hypothesis is that of an altered metabolism of the cerebral cells dependent upon exhaustion and diminished influx of stimuli. Quite recently two new theories have been promulgated; one attributes the causation of sleep to an internal secretion of the pituitary body; the other makes it due to osmosis.

3. "The secretion of the digestive fluids is governed by the action of the nervous system, so that they are poured into the alimentary canal during the digestive process as they are required. The saliva is continuously secreted in sufficient quantities to keep the mouth moist, but the quantity formed is greatly increased by the sight or idea of food, as well as by the actual presence of food in the mouth, or the savory smell of food acting on the olfactory nerve.

"Stimulation of the mucous membrane of the stomach gives rise to increased vascularity, also to a copious secretion of gastric juice. It is probable that the food acts directly upon a local nervous mechanism in the wall of the stomach, possibly Meissner's plexus, yet it is certain that the secretion of the gastric fluid is more or less under the influence of the central nervous system. This is seen in the manner in which the digestive function is arrested by fear, anger, and other mental conditions. Moreover, the secretion of the gastric juice commences before food is actually introduced into the stomach, as the smell, taste, or idea of food stimulates its glands to activity. As division of the vagus below the origin of the recurrent branch during digestion causes the gastric mucous membrane to become pale, and diminishes the secretion of gastric juice, it may be inferred that this nerve is an efferent nerve, the action of which normally inhibits the vasoconstrictor action of the sympathetic.

"The secretion of the pancreas, like that of the salivary glands, is undoubtedly under the control of the nervous system, and a large flow of pancreatic juice occurs immediately food is taken; and a second but less copious flow takes place about four hours afterwards, probably when the principal discharge of chyme from the stomach into the duodenum takes place.

"In the intestine the rich nervous plexus of Meissner, which is found in the submucous tissue, is concerned in regulating the secretion of the glands in the intestinal wall. Similar plexuses are found in the esophagus and stomach, and in the latter, it has been already stated, a local nervous mechanism probably regulates the act of secretion."—(*Aids to Physiology.*)

4. See Gray's "Anatomy" (1908), page 1330.

5. The volume of the brain is increased during expiration, and is diminished in inspiration. This can be observed in infants before the fontanelles are closed, and in adults when the brain is exposed. "With the act of expiration the flow of blood in the arteries is favored and the current in the veins is retarded. If the effort be violent, the valve at the opening of the internal jugular may be closed. This act would produce an expansion of the brain, not from reflux by the veins, but from the fact that the flow into the chest is impeded, and the blood, while passing in more freely by the arteries, is momentarily confined. With inspiration the flow into the thorax is materially aided, and the brain is in some degree relieved of this expanding force."—(Flint's *Physiology.*)

6. *Glycogen* is chiefly formed from the carbohydrates The liver cells act upon the dextrose into which the carbohydrates have been converted by the action of the ptyalin

and amylopsin of the digestive juices. This *may* occur by a simple process of dehydration:

$$C_6H_{12}O_6 - H_2O = C_6H_{10}O_5$$

But the precise process by which it occurs in the liver cells is not known. At a subsequent period the glycogen is transformed into dextrose and is returned to the circulation. Hence the blood of the hepatic veins contains more sugar than the blood of the arteries, and these latter more than the blood in the veins (except the hepatic). This is the generally accepted view, but it is denied by Pavy, and the whole subject is in a state of uncertainty.

The *function of glycogen* is to form a temporary reserve supply of carbohydrate material that is stored up in the liver during digestion, and made use of between meals; at the same time the percentage of sugar in the systemic blood is kept nearly constant.

7. The brain of man, as compared with that of lower animals: (1) Is greater in size and weight; (2) shows a greater complexity of the convolutions; (3) has frontal lobes relatively greater in size and complexity; (4) has temporo-sphenoidal lobes less prominent; (5) the fissure of Sylvius is nearly horizontal; and (6) the fissure of Rolando is more distinct.—(From Kirkes' *Physiology.*)

8. This procedure is of very limited application because of the necessity of finding large nerves in the neighborhood; it is utilized nearly exclusively in the upper extremity; it seems to make no difference whether a sensory nerve be grafted to a motor or to a mixed nerve—or vice versa. The object is to switch an interrupted nerve impulse into a neighboring sound nerve, and then have it returned to the original nerve (lower down), and so transmitted to its final distribution as though there had been no interruption.

9. See Cunningham's "Anatomy" (1909), page 401; or Gray's "Anatomy" (1908), page 376.

10. The function of a nerve is determined by dividing the nerve and then observing whether there is any loss of sensation, or muscular paralysis, or absence of secretory function, or degeneration of tissue.

11. A destructive lesion in the posterior limb of the internal capsule will cause hemiplegia of the opposite side, followed by contractures; and also hemianesthesia, in which the special senses may be included.

12. (*a*) The secretion of sweat is chiefly under nervous control; and (*b*) but slightly under vascular control. "The relation of the secretion of perspiration to the temperature of the body, and the amount formed, is under the control of the nervous system. An increased supply of blood to the skin, the result of vasomotor inhibition, acts only indirectly in increasing the secretion, which is under the direct control of special secretory nerves. This can be shown by the stimulation of a cutaneous nerve even after the blood supply has been cut off. Stimulation of the sciatic of the amputated limb of an animal will produce a discharge of sweat upon the foot. The copious sweat produced on the pale, cold, anemic skin by fear and in some forms of death are evidence that sweat, like saliva, may be secreted in considerable quantity without any increased, and, indeed, with a greatly diminished, blood supply."—(*Aids to Physiology.*)

BACTERIOLOGY.

1. BLASTOMYCETES. *Structure:* A protoplasmic body surrounded by a double-contoured capsule. Sometimes drops of fat, granules, and vacuoles are seen; the presence of a nucleus is doubtful. Sometimes they appear as long, cylindrical hyphæ. *Multiplication* is by budding; sometimes also by sporulation.

BACTERIA. *Structure:* A protoplasmic body surrounded by a cell wall and nucleated, often flagellated, and sometimes granular. *Multiplication* is by fission, sometimes also by sporulation.

2. *Bacillus coli communis* (*a*) shows colonies in twenty-four hours on gelatin. The deeper colonies are round and brownish; the more superficial ones are larger and more diffuse; the edges are dentate; the gelatin is not liquefied. (*b*) The milk coagulates, becomes acid, gas is given off, and a fecal odor is observed. (*c*) Dextrose is fermented, and gases are formed (mainly CO_2 and H_2, generally two parts of H_2 to one of CO_2). (*d*) Lactose is fermented, and gases are formed (mainly CO_2 and H, but in less constant proportion than in dextrose).

3. Absence of oxygen is necessary for the growth of the tetanus bacillus; otherwise the conditions are much the same as for other bacilli. The appearance of a stab culture, in gelatin, about the sixth day, is that of a fir tree.

4. *Difference between an antitoxin and a bacterial vaccine:* "The antitoxic sera act directly upon the poison secreted by the living bacterial cell and neutralize its toxic property, while the bacteriolytic sera affect the bacteria themselves and destroy them or paralyze their action. Since the antibacterial sera are without effect upon the formed toxin, they are mainly useful in practice as a means of protecting against the bacterial invasion, while the antitoxic sera (*e.g.* diphtheria) may be employed to combat an infection already in progress. Broadly speaking, the latter are curative, the former protective."—(Jordan's *Bacteriology.*)

5. *Four pathogenic anaërobic bacteria: Bacillus tetani, Bacillus œdematis maligni, Bacillus œrogenes capsulatus,* and *Bacillus botulinus.*

6. *Differentiation between Bacillus tuberculosis and Bacillus lepræ:* (1) It is claimed that the leprosy bacillus is stained by an exposure of six or seven minutes to a cold, saturated, watery solution of fuchsin, and retains the stain when subsequently treated with acid alcohol (nitric acid 1 part to alcohol 10 parts). When treated for the same length of time the *Bacillus tuberculosis* does not ordinarily become stained. (2) The leprosy bacilli are found in enormous numbers, especially in large vacuolated cells (lepra cells), and lie in the lymph spaces. They are frequently beaded and lie in masses which have been likened to a bundle of cigars tied together. It is necessary to examine for long periods of time smears made from tuberculous lesions of skin before finding a single organism. (3) Leprosy bacilli have not surely been cultivated. (4) Injected into guinea-pigs, they do not produce lesions.

7. *To make a gelatin plate culture:* Melt three tubes of gelatin, and let them cool in a water bath to about 30° C. Sterilize the platinum wire. Inoculate tube 1 with a platinum loopful of the material to be plated (pus from the furuncle) and mix thoroughly. Replace the cotton plug, and take care that it does not get soiled. From tube 1 transfer two loopfuls to tube 2, and mix, and replace plug as before. From tube 2 similarly transfer two loopfuls to tube 3, and mix, and replace plug as at first. Then pour the contents of each tube into a sterile Petri dish; heat the neck of the tube as soon as the plug is removed, insert it under the edge of the lifted Petri dish cover and pour quickly.

8. *Ten pathogenic bacteria that are Gram positive: Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Streptococcus pyogenes, Pneumococcus, Bacillus anthracis, Bacillus tuberculosis, Bacillus lepræ, Bacillus diphtheriæ, Bacillus tetani, Micrococcus tetragenus.*

9. The *opsonic index* is the relative amount of opsonins in a serum, as compared with the normal standard. It is obtained by dividing the average number of bacteria taken up by a leucocyte under the influence of a given serum by the average number taken up by a leucocyte under the influence of a standard normal serum.

10. To sterilize (*a*) a culture tube of gelatin: Put it in an Arnold sterilizer on three successive days, or in the autoclave at about 8 or 9 pounds' pressure for ten minutes. (*b*) A glass container with rubber stopper: Take out the stopper, clean it with soap and water, and let it stand for an hour in a solution of bichloride of mercury 1:1000, and then wash with sterile water; plug the glass with non-absorbent cotton and put it in a hot-air sterilizer at 170° C. for one hour. (*c*) A platinum needle in a glass handle: Heat the needle in an alcohol flame till red hot, and then allow to cool.

CHEMISTRY.

1. The poison in most headache powders is Acetanilid. It produces a sense of chilliness, cold perspiration, cyanosis, pulse soft and slow, respirations slow and shallow, dizziness, dyspnea, collapse, and coma. *Antidote,* strychnine.

2. Sulphur, mercury, phosphorus, oxygen, carbon, and iodine.

3. The presence of an abnormal quantity of chlorine in drinking water generally indicates sewage contamination.

4. *Gmelin's test for bile pigments:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

The *Pettenkofer test:* Dissolve one or two drops of a solution of cane sugar 1:4 in the liquid to be examined; shake the mixture and float it carefully upon concentrated H_2SO_4. In the presence of bile acids the solution becomes turbid at the zone of junction of the two layers; this is soon replaced by a deep reddish purple zone, which extends upward and downward.

5.

	COW'S MILK.	WOMAN'S MILK.
Reaction	Alkaline or amphoteric.	Alkaline or amphoteric.
Specific gravity....	1028 to 1034.	1026 to 1036.
Percentage of fats.	3 to 4.	3 to 4.

6. *Cholesterin* is found in the bile; *pepsin*, in the gastric juice; *trypsin*, in the pancreatic juice.

7. In *phosphorus poisoning* the *antidotes* are: (1) Solution of potassium permanganate (1 per cent.); this oxidizes the phosphorus, forming phosphoric acid and phosphates; the potassium permanganate itself becoming manganese dioxide. (2) Old, acid, oil of turpentine; this is said to combine with the phosphorus to produce a non-poisonous substance.

8. (*a*) *Capillary attraction* is the force which attracts fluids in contact with small tubes thrust into them, so that the fluid is drawn up above the surface of the liquid in the containing vessel.

(*b*) *Absorption* is the process by which one substance is taken up or into another by molecular action.

(*c*) *Diffusion* is the gradual and spontaneous passage of one gas into another gas, or of one liquid or dissolved substance into another liquid.

(*d*) and (*e*) If two liquids be separated from each other by a membrane each will pass through the membrane into the other; this process is called osmosis; they do not pass with equal rapidity. *Endosmosis* is the term used to denote the more rapid osmosis, and *exosmosis*, the slower. These terms are also used to denote the direction (inward or outward osmosis, respectively).

9. Nitrogen is chiefly eliminated from the body as urea. *Chemical properties of nitrogen:* It is a gas, colorless, odorless, tasteless; it is not combustible, and does not support combustion; is but slightly soluble in water; it is very slow to enter into combination; it is not poisonous, but it is incapable of supporting respiration.

10. *Chemical composition of various renal calculi:* Uric acid, sodium urate, ammonium urate, calcium oxalate, calcium phosphate, ammonium magnesium phosphate; occasionally, cystin, xanthin, and urates of potassium, calcium, and magnesium.

11. Chemical antidote for (*a*) *Phenol*, sodium sulphate; (*b*) *arsenious oxide*, freshly prepared solution of ferric hydroxide; (*c*) *sulphuric acid*, magnesia; (*d*) *mercuric chloride*, white of egg; (*e*) *oxalic acid*, lime water.

12. *Urates* show a pinkish color, and dissolve on warming the urine. *Uric acid* is recognized by its crystalline form, and by the murexide reaction. The *murexide test* is: Add a little dilute nitric acid to the urine, evaporate to dryness, a yellowish-red residue is left, add a few drops of ammonia, the residue turns to violet. This is due to the formation of murexide (or purpurate of ammonia).

GENERAL DIAGNOSIS.

11. See French's "Practice of Medicine" (1907), page 1030; or Osler's "Practice of Medicine" (1909), page 946.

12. See French's "Practice of Medicine" (1907), page 852; or Osler's "Practice of Medicine" (1909), page 550.

PATHOLOGY.

1. *Degeneration* is a pathological process in which abnormal substances are formed within living cells, or the entire cells are transformed into abnormal material.

Atrophy is decrease in the amount of a tissue, owing to diminution in size (simple atrophy) or number (numerical atrophy) of the histological elements of which it is composed. There are also loss of weight and impairment of function. There is no definite disease of the cells or tissues; frequently the two conditions (degeneration and atrophy) merge, and it may be difficult to draw a dividing line between them.

2. In *tabes dorsalis* the posterior columns of the spinal cord and the posterior nerve roots are involved. The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

3. See French's "Practice of Medicine" (1907), page 239; or Osler's "Practice of Medicine" (1909), page 15.

4. For the changes, in general, see French's "Practice of Medicine" (1907), page 939; or Osler's "Practice of Medicine" (1909), page 412. As to the distinction asked in the question, we can find no information.

5. The average blood pressure in adults fifty to sixty years of age is about 100 to 145 mm. mercury. If this pressure is exceeded for a considerable time there will be hypertrophy and dilatation of the heart; possibly, also, bursting of a blood-vessel, with its consequences.

6. Sarcoma is the most usual malignant growth in bone; the reason is that bone is a connective tissue, and sarcoma is the only malignant tumor of the connective tissue type.

7. Cerebral embolism most frequently occurs as a result of vegetations of an endocarditis. The artery of the Sylvian fissure is most likely to be affected, owing to anatomical conditions by which the embolus takes the most direct route from the left side of the heart to the brain (through the aorta, left common carotid, internal carotid, middle cerebral, and so to artery of Sylvian fissure). The anterior cerebral artery may also be obstructed; or the posterior cerebral (in which case the embolus travels along the vertebral and through the basilar).

8. See French's "Practice of Medicine" (1907), page 454; or Osler's "Practice of Medicine" (1909), page 252.

9. See French's "Practice of Medicine" (1907), page 599; or Osler's "Practice of Medicine" (1909), page 820.

10. In old age the walls of the bladder grow thicker, and the capacity becomes smaller; in men the prostate gland enlarges; urinary troubles follow, caused partly by the above and partly by diseases of the kidneys or other organs. All the resisting and recuperative powers of the body are diminished, the reparative processes no longer act, or act feebly and slowly; the nutrition of the tissues is enfeebled; hence diseases tend to become chronic. Degenerative processes are also common.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), pages 480 and 916; or Hirst's "Obstetrics" (1909), pages 263 and 674.

2. There is no fixed time for the ligation of the cord; as a rule it should not be ligated till it has ceased to pulsate, unless there is some urgent reason to the contrary. Dry, aseptic cotton or gauze (borated or salicylated) makes the best dressing. It should be kept dry and aseptic, and, if possible, be touched by no one but the physician. The dangers of improper dressing are: Infection, peritonitis, and death of the child.

3. *Injuries which may occur to the birth canal during labor:* Lacerated perineum, tears and abrasions of labia, injuries of blood-vessels, laceration of vagina, laceration of vulva, injuries to levator ani muscle, lacerations of cervix, rupture of uterus, instrumental perforation of uterus, inversion of the uterus.

4. ANESTHETICS are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required.—(From King's *Obstetrics*.)

Dangers: It lessens the efficiency of the uterine contractions; it predisposes to postpartum hemorrhage; and, if given too freely, may be followed by headache, nausea, and vomiting.

5. PREMATURE RUPTURE OF THE MEMBRANES. *Causes:* Deformed pelvis, shoulder presentation, unusual friability of the membranes, endometritis. The progress of labor is lengthened and rendered more difficult; hence infection is

more likely. It conduces to laceration of the cervix, rupture of cervix, prolapse of funis, maternal exhaustion and shock, and fetal death.

6. See Williams' "Obstetrics" (1909), page 140; or Hirst's "Obstetrics" (1909), page 86.

7. *Adherent placenta* is not common. It cannot be expressed. There is no descent of the cord. Pressure on the fundus causes a thrill of the cord; there is hemorrhage.

In *retained placenta* the opposite of the above will be observed. For *treatment* see Williams' "Obstetrics" (1909), page 301; or Hirst's "Obstetrics" (1909), pages 434 and 436.

8. See Williams' "Obstetrics" (1909), page 211; or Hirst's "Obstetrics" (1909), pages 200 and 389.

9. *False pains* are irregular uterine contractions which occur before the beginning of labor, and which may be either painful or painless, and which do not cause the "show," nor yet dilate the os.

True pains are uterine contractions occurring at the beginning and lasting through the first two stages of labor. They are usually very painful; they advance labor, dilate the os, and cause the "show."

10. See Williams' "Obstetrics" (1909), pages 833 and 836; or Hirst's "Obstetrics" (1909), pages 593 and 597.

11. See Williams' "Obstetrics" (1909), page 81; or Hirst's "Obstetrics" (1909), pages 57 and 61.

The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

12. See Williams' "Obstetrics" (1909), page 824; or Hirst's "Obstetrics" (1909), pages 614 and 616.

GYNECOLOGY.

1. "Many cases of displacements are so complicated by prolapsed and adherent ovaries, by advanced disease of the ovaries and Fallopian tubes, by tumors, by inflammatory exudates, or by peritoneal adhesions that replacement is impossible, or, replacement being possible, the pessary is either intolerable from pain or proves inadequate to sustain the uterus. Such cases, unless relievable by non-surgical measures, furnish a definite indication for surgical treatment."—(Dudley's *Gynecology.*)

2. *Pelvic hematocele* is an accumulation of blood in the pelvis, due to rupture of a blood-vessel; it is generally due to rupture of a tubal pregnancy, or to a tubal abortion. *Symptoms:* Pain, which is sudden and severe, over abdomen and pelvis; nausea, cold perspiration, cold extremities, pulse rapid and weak, pinched features, and shock.

3. PELVIC CELLULITIS. *Pathology:* "Pelvic cellulitis is the inflammation of the connective tissue in the pelvis, above the pelvic diaphragm. It is particularly found in the broad ligaments, the surroundings of the cervix, and the sacro-uterine ligaments. It may be acute or chronic. The former may arise from a tear in the cervix extending into the parametrium, spread from the interior of the uterus, or originate in the depth of bruised tissue. Generally it is combined with peritonitis, lymphangitis, or phlebitis. It is as a rule unilateral. It may be traumatic or septic. Both are caused by germs, but the former is due to simple saprophytes, the latter to pathogenic microbes. Either of them may be puerperal or non-puerperal. The traumatic spreads in the loose connective tissue lying between the denser membranes; the septic does not respect any boundary. First, there is a stage of infiltration, which may end in resolution, induration, or suppuration. Of all pelvic inflammations, cellulitis is the one most prone to end in suppuration. The pus spreads, and the abscess may open in a way similar to that followed by an intraperitoneal one; but while the puerperal form has a tendency to break through the skin, the non-puerperal form usually opens into one of the hollow organs. Rupture into the peritoneal cavity is rare. Cellulitis may end in cicatricial retraction, causing uterine displacement. Indurated tissue is apt to suppurate after a long time. *Physical signs:* The patient may have a chill, there is a rise in temperature; the pulse is accelerated; she has pain in the lower part of the abdomen, and perhaps vesical and rectal tenesmus; she has no appetite; and her tongue is furred. But the pain does not come on so suddenly as in peritonitis, and is not so severe. There is less tendency to vomiting, and no meteorismus. By vaginal examination we find the vagina hot, swollen, and tender. If the seat of inflammation is in the broad ligament, we find at the side of the uterus a tumor that is sensitive on pressure and crowds the uterus to the opposite side. If both ligaments are inflamed the uterus is lifted up. If the sacro-uterine ligaments are inflamed we feel one or both folds at the top of Douglas' pouch swollen and sensitive. More rarely the swelling is situated behind or in front of the uterus. If the affection extends into the iliac fossa the corresponding leg is drawn up. If the tissue suppurates the swelling becomes softer, but rarely distinctly fluctuating, and there is an increase in the fever."—(Garrigues' *Gynecology.*)

4. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix. The cause may not be in the woman, but in the man.

5. In *pudendal hernia:* There is a tumor which is soft, insensitive, and rounded; and which is apt to disappear with a gurgling sound on pressure or if the patient is put in the knee chest position; it is tympanitic on percussion, and may give an impulse on coughing. In *pudendal hematocele:* There is generally a history of trauma, no impulse on coughing, no resonance on percussion, and it is not reducible.

6. By *perineorrhaphy* is meant the various operations that are performed for the repair of lacerations of the perineum in the female.

7. *Chronic endocervicitis. Etiology:* Bacteria, especially gonococci; lacerations of the cervix, tumors, polypi, and excessive coitus. *Pathology.* The inflammation may spread, causing endometritis, salpingitis, ovaritis and peritonitis; the body of the uterus is very apt to become involved. The mucous membrane becomes congested, thickened, and everted, and the cervix appears hypertrophied; the secretion is increased and is thick, ropy, viscid and profuse. The cervical epithelium becomes eroded and the glands become enlarged.

8. See Rose and Carless' "Surgery" (1907), page 1285.

9. In both cases the prognosis is bad, a fatal result being inevitable unless timely and thorough operation is performed. Cancer of the body of the uterus progresses much slower than cancer of the cervix, and therefore in the former the disease will last longer. In cancer of the cervix the only hope lies in an early diagnosis, followed by operation. Hysterectomy gives much better results in cancer of the body of the uterus than it does in cancer of the cervix; the ratio of cures being about 60 per cent.: 5 per cent. So the prognosis may be said to be better in cancer of the body of the uterus.

10. A *tampon* is a small roll of absorbent cotton, about 2½ x 1 inches, and is inserted into the vagina either with or without some medicinal substance. Around the center of the tampon is a strong string, long enough to hang out from the vulva, and by which the tampon can be removed. The details of the mode of use will depend upon the condition for which the tampon is used. In any case the patient's bowels should be empty, and as a rule she is placed in either the dorsal or knee-chest position. The tampons are removed after about 36 hours, and a douche is then taken. The *purposes* of a vaginal tampon are: For controlling hemorrhage, either vaginal or uterine; to exert pressure; to support the uterus; as a means of applying medication locally; and for depleting inflammatory conditions.

11. *Chancre of vulva* is the first lesion of syphilis, is due to infection, has a long period of incubation, is generally single, is not as a rule painful, only occurs once in a patient, buboes are apt to follow. *Herpes of vulva* is a local neurosis, is due to irritation, has no incubation period, consists of multiple vesicles appearing in crops, tingles and itches, has no lymphatic involvement.

12. *Muscles of perineum:* Transversus perinei, sphincter vaginæ, erector clitoridis, compressor urethræ (and levator ani). *Functions of perineal body:* It holds in position the lower end of the rectum, vagina, and urethra and enables them to perform the functions of defecation, coitus, parturition, and urination; it strengthens the pelvic floor.

HYGIENE.

1. See French's "Practice of Medicine" (1907), page 267; or Osler's "Practice of Medicine" (1909), page 234.

2. See French's "Practice of Medicine" (1907), page 107; or Osler's "Practice of Medicine" (1909), page 96.

3. *A septic tank* is a specially constructed tank for the treatment of sewage; in it the sewage as such is destroyed, and new substances are built up in its place. In *Cameron's septic tank* system "the sewage is first led into a tank from which air and light are excluded. Digestive changes take place in the sewage within this tank as the result of anaërobic bacterial action, which is favored by the dark-

ness, the absence of air, and the perfect stillness at which the sewage is maintained. Under these circumstances much of the solid matter is rendered soluble and dissolved."—(Notter and Firth's *Hygiene.*)

4. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust and admit of his spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practicing lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. * * * The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel night-gown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed daily with alcohol and water."—(Thompson's *Practical Medicine.*)

5. See French's "Practice of Medicine" (1907), page 474; or Osler's "Practice of Medicine" (1909), page 28.

6. The best means of fumigating by formaldehyde gas are: (1) By Trillat's apparatus, which "allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, and the gas and vapor passing directly into the room. The apparatus may be operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated. (2) In Schering's method the solid paraform is heated in a receptacle over an alcohol lamp, and is especially valuable in disinfecting small rooms, closets, etc. (3) The cheapest and most common form develops the gas directly by the oxidation of methyl alcohol, the vapors of the latter passing over or through tubes or coils of heated metal.—(Gould and Pyle.)

To *fumigate by chlorine:* For 1,000 cubic feet of space pour two ounces of H_2SO_4 and three ounces of water, previously mixed and cooled, upon eight ounces of NaCl and two ounces of MnO_2. The fluids must be mixed slowly and with care, and the salts should be in an earthen vessel upon a bed of sand. The generating apparatus should be high because chlorine gas is heavy.

To *fumigate by sulphur dioxide:* For each 1,000 cubic feet of space, three pounds of sulphur are burned, care being taken to prevent accidents. In all cases, all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

7. Gonorrhea exerts an inhibitory influence upon the procreative capacity of both man and woman; in the man it may cause oligospermia, azoospermia, spermatozoa without power of movement, epididymitis, stricture, etc.: in the woman it may cause vaginitis, endocervicitis, endometritis, salpingitis, ovaritis. Each of these may interfere with propagation. Syphilis may cause disease or death of the fetus. Hence both gonorrhea and syphilis tend to prevent the propagation of the human species.

8. See French's "Practice of Medicine" (1907), page 499; or Osler's "Practice of Medicine" (1909), page 45.

9. See French's "Practice of Medicine" (1907), page 311; or Osler's "Practice of Medicine" (1909), page 127.

10. *Incubation period of: Plague*, is about 2 to 7 days; *Smallpox*, about 12 days; *Diphtheria*, about 2 to 7 days; *Scarlatina*, about 1 to 8 days; *Measles*, about 7 to 14 days.

11. The object of traps is to prevent the passage of sewer air into houses. If there were no traps sewer air would enter the houses, and there would follow symptoms such as: Vomiting, diarrhea, headache, prostration, pallor, languor, loss of appetite, and susceptibility or liability to certain infectious diseases would be increased.

12. *Two types of water filter:* 1. The first has a filtering medium of carbon (charcoal), or iron. Such filters strain off the grosser suspended impurities and make the water more palatable through aeration. The best, when new, slowly oxidize organic matter, lessen hardness, diminish nitrites and ammonia, and increase nitrates. They do not remove disease germs; but may, after a few days' use, increase the number of bacteria. 2. The second type provides bacteriologically pure water, but has no effect on the chemical constituents in solution; its pores are so fine as to strain off all microorganisms. Of this class are the Pasteur-Chamberland filter of unglazed porcelain, and the Berkefeld filter of infusorial earth.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of September 10, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	617	148
Diphtheria	143	8
Measles	60	6
Scarlet Fever	83	2
Smallpox	—	—
Varicella	19	—
Typhoid Fever	165	12
Whooping Cough	60	3
Cerebrospinal Meningitis	3	6
Malarial Fever	—	—
Totals	1,150	185

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended September 9, 1910.

STREET DUST AS A FACTOR IN SPREADING DISEASE; METHODS OF REMOVAL.*

BY JAMES M. ANDERS, M.D., LL.D.,

PHILADELPHIA.

PROFESSOR OF MEDICINE AND CLINICAL MEDICINE OF THE MEDICO-CHIRURGICAL COLLEGE, ETC.

WHILE no one now believes, as did the Greeks and Romans in the earlier centuries of the Christian era, that devastating epidemics of pestilential diseases are visitations of Providence or angry deities, yet the fact that the majority of human ills result from neglect of certain precautionary, health-fostering measures, which an ever advancing science has placed at man's disposal, is not fully realized. There is no lack of unanimity of opinion among health officials, sanitarians, and physicians as to the evil consequences to the public health of the filth and dust of our streets. It may be put down as an axiom that cleanliness of our city highways and freedom from street dust is not less important to the municipality than a pure drinking water supply.

The question of the noxious influences exerted by street dust may be conveniently considered under two heads: (*a*) the effects of the inhalation of non-infectious street dust; and (*b*) street dust as a vehicle for conveying disease germs, or the influence of infective dust.

The effects of the inhalation of non-infectious street dust.—The far-reaching ill-effects of floating matter in the air have not been sufficiently emphasized by sanitarians and physicians in the past, and it must be conceded that the conditions essential to the generation and the diffusion of dust in the atmosphere of our thoroughfares are prevalent to a greater degree at present than at any previous period of time. Again, those charged with the removal of the dust from our streets have failed to cope successfully with the situation in the past.

The composition of the filth and dust ordinarily found in the streets varies decidedly in different cities, and also in different portions of the same city, depending upon the character of the predominant manufacturing establishments which discharge their refuse into the streets, the character of the fuel used, the degree of care exercised by the populace, and, lastly, the nature of the pavement and of the soil in the vicinity.

W. Gilman Thompson[1] regards the term street "dirt" as comprising any or all of the following ingredients: "(1) The ashes, house sweepings, etc., which are freely blown about from exposed ash carts and ash barrels. (2) The excrement of horses and dogs voided in the streets, to become dried, pulverized, and distributed by winds and traffic. (3) The irritating powdered asphalt, ground from the surface of the pavements, and often mixed into a slimy paste with mud, horse dung, and the petroleum drippings from automobiles. (4) Pulverized earth, plaster, iron dust, cement, etc., derived from buildings undergoing construction or demolition, and carried about the streets in loosely constructed wagons. (5) The earth from street excavations, usually impregnated with sulphides and other products from leaking gas mains. (6) The soot from chimneys, which eventually settles in the streets and in the winter becomes visible by blackening the snow. In addition, as less general filth factors, may be added: (7) The garbage which in the tenement districts is frequently overturned into the street, especially after heavy snowstorms, when its removal is neglected. (8) Human excrement which in the crowded tenement neighborhoods is often voided by children or adults in blind dark alleys and ill-lighted streets."

In general, street dust deposits contain mineral particles, which form mechanical irritants, organic matter, both animal and vegetable, of numerous and widely different conditions and character. The organic substances if allowed to lie in the streets for too long a period, particularly during the warm season, undergo more or less decomposition, giving rise to other and yet more powerful deleterious products.

The dust found so abundantly in our streets comes principally from two sources: first, that which results from allowing the filth and refuse of the streets to lie undisturbed until it becomes thoroughly desiccated, when it is in a great measure, at least, converted into dust, and secondly, that which is swept from the soil by wind-currents. Chimneys and smoke-stacks likewise furnish a considerable amount of the dirt deposits of the streets, as well as of the dust contained in the air of city streets, particularly in the manufacturing districts and along the route of urban railroads.

There is still another constituent of dust which it should be the pride of every community to eliminate, since its ill consequences are far-reaching: I refer to dessicated human expectoration. Little does the general public appear to understand that in street spitting we have one of the worst examples of the violation of sanitary laws and decency that could be cited. Sputum harbors various disease germs, particularly tubercle bacilli and streptococci, and this fact furnishes the chief reason why the dust of our streets (into which the dried sputum enters) is so decidedly prejudicial to the public health. We need not stop here to inquire whether pathogenic implantation is the result of inhalation or ingestion of the tubercle bacillus, but that dust disseminated by air-currents is one of the principal sources of the spread of tuberculosis, is an accepted fact.

*Read before the American Climatological Association, Washington, D. C., May 4, 1910.

Following a thaw after snow-falls, uncleaned streets are covered with a slushy mud of varying depth. This germ-laden dirt adheres to clothing and shoes, and thus dragged into the houses where it dries and becomes diffused through the house-air. The important subject of household dust as a factor in the dissemination of tuberculosis and other inhalation diseases and the measures indicated in private houses, clubs, theaters, office buildings, schools and churches, to meet the demands of hygienic living, however, is one that cannot be discussed here.

Among the important primary conditions caused by the inhalation, more or less constantly of street dust (minute irritating particles entering into its compensation), are nasopharyngeal irritation, at times leading to frontal sinus disease, pharyngitis, tonsillitis, laryngitis, asthma, and bronchitis. The floating matter in the air may cause a severe conjunctivitis and in sufferers from organic affections of the heart, the irritation produced by the inhalation of street dust into lungs may call forth pulmonary congestion and edema. The physical deterioration superinduced by an atmosphere thus polluted is manifested by cough, dyspnea, and other customary symptoms of the pathologic conditions before mentioned.

It is fair to assume that these conditions may be caused by non-infectious dust, and more than this, they establish a predisposition to more serious disease of the lungs, such as tuberculosis and the pneumonias. The indirect pathogenic properties of dusty trades has received startling proof from Scurfield's[2] observations on certain occupations in Sheffield. This writer has shown that the death rate of "grinders" from phthisis is more than six times and the death rate from other respiratory diseases nearly three times that of the average male; while the death rate of cutlers from phthisis is nearly three times and from other respiratory diseases nearly four times that of the average male.

The dangers of non-infectious dust when constantly inhaled in working hours are also shown by an investigation into the causes of death among the Metal Polishers' Union of North America.[3] The deaths were with few exceptions from pulmonary tuberculosis, the tubercle bacilli finding a favorable nidus for implantation and growth in the foci of irritation set up by the dust particles. For example, the statistics for 1903 show that 45 metal polishers died, of whom 43 succumbed to some lung trouble; in 1904 there were 38 deaths among them, of which only three were due to causes other than pulmonary disease, while in 1905, 70 deaths occurred among the metal polishers, 65 of which were due to some form of lung complaint. Sandwith's[4] careful studies of various industrial diseases have yielded confirmatory results. The above figures afford convincing proof that clean, uncontaminated dust may still prove a potent factor in the etiology of tuberculosis and other pulmonary diseases, although operating in an indirect manner.

Anthracosis due to coal dust (carbon particles) and the inhalation of vegetable dust set up chronic interstitial inflammation, which predisposes markedly to pulmonary tuberculosis. The mass of dried, pulverized material swept from our streets into the atmosphere by the winds, and that whirled up in the form of great clouds of dust by the automobiles, must be inhaled by passers-by with definite, evil consequences. It has been well said that our parks and boulevards have ceased to be breathing places where the poor and middle classes can go for fresh air, and that family outings to outlying parks implies a return to their homes at night choked with dust, instead of being refreshed by their outing. If we recall the composition of street dust, as given above, principally mineral and vegetable matters, and granting that it is for the most part non-infectious, it is clear that its daily inhalation must nevertheless induce a mechanical irritation which, in turn, invites infection with the tubercle bacillus and other pathogenic organisms.

Street Dust as a Vehicle for Conveying Disease Germs, or the Influence of Infective Dust.—The extent to which street dust is contaminated with disease-bearing germs must depend largely upon the hygienic precautions exercised in a community. Speaking of the dirt factor in the causation of disease, Thompson[1] observes that it is no exaggeration to state that nine-tenths of the acute inhalation diseases and chronic catarrhal diseases are due chiefly and directly to dirt inhalation. On the other hand, the experience of Hill with the diphtheria bacillus, and of Whipple with the typhoid bacillus, show these bacteria to be for the most part harmless in dust, unless such dust was very recently infected, since they cannot long withstand light and drying. Occasionally, the germs of scarlet fever, pneumonia, and possibly whooping cough, cling to particles of floating matter or flying dust. In the case of the tubercle bacillus, according to Jordan,[5] "sputum that is completely dried so that particles are capable of floating in the air may be infective for eight or ten days, rarely longer."

Unquestionably the spitting nuisance in our public streets has been responsible for the infection of street dust with tubercle bacilli in the past. The fact is fully appreciated at date of writing that if expectoration on sidewalks and streets were everywhere prohibited the possibility of street dust becoming infected with tubercle bacilli, pneumococci, the germs of influenza, meningitis, measles, scarlatina, and other pathogenic bacteria would be reduced to a minimum. The importance of reasonable care of the sputum, if we would avoid contamination of the atmosphere of our homes, sanatoria, street cars, railway coaches and the like, has been abundantly shown by the experimental studies of Dr. Samuel G. Dixon, Health Commissioner of Pennsylvania; Dr. Irwin Hance, for the city of New York, and others.

McCarthy[6] justly incriminates the house fly as a carrier of infection. Attracted by the vegetable and animal matter found in the dust of the street, he next transports himself, bearing the germs of tuberculosis or pneumonia, to a neighboring candy or fruit store. Again, he may have visited first a typhoid fever patient, and subsequently been attracted to a nearby fruit store or candy shop.

In this connection reference should be made to the custom of exhibiting for sale food supplies, as vegetables, fruits, fish, meats and the like, in places where they are exposed to contamination by flies and street dust. The danger of infection of exposed foods with tubercle bacilli and typhoid bacilli must be great where flies have access to these and also to infected street dirt. Under these circumstances infection via the intestinal route with pathogenic organisms, such as the *Bacillus typhosus*, tubercle bacillus, and the *Bacillus coli communis* (from horses and other animals and contained in the dust), would appear to be obvious.

It must be conceded, however, that opportunities

for infection, either through inhalation of dust or the ingestion of uncooked foods, have been reduced by the well-enforced laws against spitting on the sidewalks and by the greater care exercised in the disposal of typhoid dejecta. On the other hand, we must recognize the fact that the dangers of street dust as a vehicle for conveying disease-producing organisms, and also opportunities for inhaling dust, have been infinitely increased since the introduction of the automobile as a means of transportation, for the reason that as a dust raiser that modern invention stands unique. On the other hand, the automobile tends to improve the hygienic status of city streets by removing the pathogenic possibilities of the feces of the horse.

If it be conceded that tuberculosis infection is capable of being disseminated by means of air currents and also that the dried, pulverized sputum to be found in dust is one of its principal primary sources as well as methods of extending its ravages, then it is clear that the automobile is profoundly prejudicial to public health, except means be found to successfully prevent dust formation. Finally, it is freely admitted that the indoor air, laden with bacilli containing dust, is even more dangerous than the outdoor air similarly charged.

Means of Removing Street Dust.—In view of the overwhelming mass of evidence, which proves the presence of lurking dangers of street dust, a warfare against this form of air poisoning until victory is assured would be both timely and of the utmost importance. It is not less the duty of cities, towns, and villages to provide pure air for the inhabitants to breathe than to provide them with first-class drinking water. Perhaps the principal reason why street cleaning is so indifferently and ineffectually carried out in most cities resides in the curious subdivision of work and responsibility connected therewith, whereas I feel strongly that it should be controlled solely by the health department of a municipality.

There are feasible and approved modern scientific methods adaptable to local conditions, and these are known to trained sanitarians, sanitary engineers, and physicians, who should constitute the personnel of health boards and are fitted to suggest suitable legislation where the necessity for the enactment of laws may exist. In this connection it may be pointed out that a careful consideration of modern methods of cleaning the streets has led me to the conclusion that the vacuum or pneumatic method as practised in Berlin gives the best results; it possesses two marked advantages: First, the street dirt is removed without raising any dust, and secondly, the process insures a more rapid, satisfactory, and complete cleansing than is obtainable by other methods. Quite apart from administrative efficiency and concentrated responsibility as bearing upon the question of street cleaning, the dust problem with which we are principally concerned here must be met.

True, the chronic state of filthy, dust-covered streets tends to maintain and exaggerate under the action of gusty winds floating matter in the air, and equally true is it that properly cleaned streets would go a long way toward the effectual removal of the atmospheric dust, but this menace to health would not be entirely overcome so long as pavements having dust-producing properties are used. In many suburban settlements, towns, villages, noted resorts, and public highways in which it would be impracticable to remove all of the street dirt and filth deposits, means to suppress dust must be provided. It is quite within strict truth to affirm that many resorts have been rendered uninhabitable by the dust whirled up in dense clouds by the automobile.

Moreover, the inspiration of dust in the air can be shown to be sufficiently deleterious in its effects when carried deep into the respiratory tract to make it incumbent on the proper authorities to effect the needed arrangements so far as they are known to remove the atmospheric dust contamination. While the prospect of the removal of dust from the air by appropriate municipal legislation are not particularly encouraging at present writing, still the question of the possible influences of this agency as affecting the prevalence and mortality of pulmonary tuberculosis has been receiving considerable attention at the hands of medical authorities, sanitarians, and sociologists, and it is to be hoped that public sentiment will soon become sufficiently matured to compel the enforcement of suitable measures looking to its removal, and in no way could more substantial progress in urban sanitation be realized.

In Italy, Gaglielminetti has been waging a campaign for years on behalf of the application of crude oil to roadbeds; he has adduced convincing evidence to show that the method costs but little more than one cent a square yard, while it renders the roads more resistant and saves repairs with entire suppression of the dust. On the other hand, tests made of petroleum products to prevent dust on highways by Cristiana and Michelis have not proved satisfactory.

Again, it must be recollected that the use of crude oil is inadvisable in streets paved with asphalt, which absorbs this substance. The method of allaying street dust in cities by means of street sprinkling is to be advised and encouraged throughout the nonfreezing period of each year. It must be confessed, however, that the watering of streets in this manner is impracticable in many towns and smaller cities owing to the expense involved. Josias suggests that automobile makers should study to obviate the raising of dust; "the escapement should not point downward, the tires should be full, and the under part of the frame should be smooth. The ideal would be to have the body egg shaped, sloping up toward the back."

Among measures advised by a committee appointed by the Stuttgart Medical Society in 1907 to discuss the question of the prevention of dust were to keep the streets carefully cleaned and warning notices in regard to the dangers of dust to be placarded by the Board of Health. Slack[7] well says: "Street sweeping at night, such as is usual in market districts, is to be commended, thus avoiding the stirring up of large quantities of dust during the day when the streets are crowded. Oiling and watering the streets are wise sanitary precautions, and money spent on these means of keeping our streets free from dust is saved a hundred times over in the health of the people."

It is in accordance with the eternal fitness of things that the American Climatological Association should wage a campaign against dust-laden street air, and thus increase its powers of ministering to the welfare of the general public. Such a great task could not be carried out, however, except by the creation of separate commissions for the different large cities and sections of the United States in which little or no attention has been paid to the question of combating street dust, and these should

work through or in conjunction with local health departments.

I would further submit the practical suggestion that a committee of the American Climatological Association be appointed to consider the subject from its hygienic and medical aspects, and to make a report at the next annual meeting. The legitimate scope of this committee should include an appeal to the mayors of all cities, requesting them either to appoint special commissions or to urge existing bureaus of health to study the problem with special reference to the good results already obtained in certain of the larger municipalities of this country with a view to overcoming the unhealthful conditions to which an unsuspecting public is now well-nigh constantly subjected.

SURGERY IN ITS RELATION TO NERVOUS PATIENTS.*

By LOUIS N. LANEHART, M.D.,
HEMPSTEAD, L. I., N. Y.,
SURGEON-IN-CHIEF HEMPSTEAD HOSPITAL.

The relation of surgery to that large class of patients often erroneously called nervous, neurasthenic, or hysterical has been more closely defined since the recent advances in diagnosis and the reclassification of nervous diseases.

If we divide such cases into classes we find they fall most readily into the following groups:

(1) Organic disease with nervous symptoms. This class may include any surgical condition, but nervous symptoms are particularly manifest in the ptoses and malpositions of the abdominal viscera, defects in the genitourinary tract and exophthalmic goiter. (2) Nervous disease accompanied by or complicated by a surgical condition. (3) Nervous conditions associated with somatic symptoms without demonstrable organic lesion.

In the consideration of the first group the nervous symptoms may so mask the organic condition that diagnosis may be mistaken, or, what is of almost equal disadvantage to the patient, delayed. It would seem that not sufficient emphasis has been laid on the fact that neurasthenia and its more recently named kindred condition, psychasthenia, are comparatively rare diseases, *per se*, and that a most rigid examination may reveal a grave medical, or, more frequently, surgical condition, whose presence is not suspected by the patient himself. Treatment of such a condition, whether medical, psychic or Emmanuel, is not advantageous so long as the organic condition remains unchanged. Attention should therefore be directed to the relief of the organic condition when discovered, but that does not mean of necessity immediate operation. In my opinion the recovery of many cases has been retarded and the completeness of the cure jeopardized by neglecting the fore-treatment or preoperative treatment of the patient. This should include rest, quiet, carefully supervised hygiene, and such other means as may be appropriate to place the patient in as good physical condition as is possible before operation.

This may present a perplexing dilemma to the medical advisor as an operation that is imperatively necessary, from the physical standpoint, may be such a strain on the vital reserve that it leaves the patient nervously bankrupt by the strain of the operation which was designed for the amelioration of the nervous condition. This calls for a most careful review of the patient's condition, mental, nervous and physical, before any operation is attempted and the delay of operation, if possible, until a near-equilibrium has been restored.

The importance of mental rest, combined with carefully supervised hygiene after operation, including such exercise, massage, etc., as may be advisable or available in each case, is capital; and no greater error could be made than to suppose such a person on the way to recovery merely because the repair of the surgical procedure has progressed favorably to healing, and under no circumstances should they be permitted to resume their ordinary activity until in the judgment of their advisor they have a sufficient nervous balance to enable them to withstand the strains which are unavoidably present on their resuming a normal activity. Neglect or slighting of such after-treatment may precipitate not only a renewal but in all likelihood an intensification of the nervous symptoms. This emphasizes the importance of the non-surgical treatment of such cases and the fact that the surgical treatment is but a phase of the general care of the patient though an essential one.

In the presence of any organic nervoous disease, such as the spinal scleroses or neuritis with secondary degenerations, any surgical condition which arises must be met by palliation unless such condition compels radical operation to save the life of the patient. This is true even in a stronger sense when there are any evidences of general trophic change or the viscera show pathological conditions dependent on, or concomitant with, the causative disease. There are numerous incidental conditions occurring in the course of nervous diseases which may by proper treatment be so ameliorated that the patient can be made more comfortable and endure the original condition with greater resistance; but in all cases except when absolutely necessary to preserve the patient's life, the advisability of operation depends rather on the course and prognosis of the nervous complaint than on the prognosis of the allied or concomitant surgical disease.

In the group mentioned under the head of nervous conditions with somatic symptoms but no demonstrable lesion, the patients generally present an obsession of surgical disease or have been informed, frequently erroneously, that their symptoms could be accounted for by some surgical lesion, or, having tried all other methods, take in desperation a surgical operation as their final hope. While it is not the intention to recite cases, one of this kind may be adduced as this patient has been under observation for several years.

J. F., a successful business man, for ten years has complained of a "feeling" in his abdomen. This is located below the ensiform cartilage, is not changed by the ingestion of food, is always present, and particularly so when harassed, or worried, or tired. The patient is well nourished and physical examination is negative. He has been to several rest

*Read May 31, 1910, at the annual meeting of the Queens-Nassau Medical Society.

cures, sanatoria and health resorts, where his only change is a gain in weight. When he returns to business he drops to his normal and stays there. He has been seen by the most eminent consultants in New York, Philadelphia, and Baltimore; has followed out various treatments and diets to no result, and has been told that he has a gastric neurasthenia. Gastric analysis by an acknowledged expert showed no abnormality in stomach digestion, and examination of the feces showed nothing abnormal. At the suggestion of this last-mentioned practitioner he welcomed with enthusiasm the removal of his appendix. This was done a year ago; the appendix showed one slight kink, but no obstructions, and otherwise was normal; there was an uneventful recovery and absence of gastric symptoms until he was allowed up, when they came back with full force. At present the patient is the same as he was ten years ago with a somewhat diminished regard for the medical profession, though he is much pleased to know he has no abdominal disease, as a careful examination was made when the appendix was removed. This represents one condition and what surgery did for him. Here the question arises, "To what extent is a surgeon justified in undertaking surgical interference at the behest of the patient when he feels confident that no surgical condition is present; where all the symptoms are subjective?"

The notorious uncertainty of external abdominal diagnosis, in many instances, and the numerous pathological conditions unexpectedly found at operation should lead one to regard a persistent impression on the part of the patient that some surgical condition is present with the most serious attention, even when such symptoms are manifested by an apparently healthy patient with a neurotic tendency, and all means of diagnosis, including exploration, should be exhausted before the medical advisor may deem himself justified in pronouncing that patient physically sound.

The fact that a patient has had a similar complaint, antedating the one for which he seeks advice, and has recovered from it under favorable hygienic surroundings should not influence us too much against the diagnosis of a possible organic lesion and cause us to dismiss such a patient with the diagnosis of neurasthenia. As an instance, peptic ulcer, either gastric or duodenal, may heal spontaneously and entail no symptoms until a renewal of the condition or cicatricial contraction has induced symptoms which, as is well known, may be entirely subjective and offer no positive signs. The same may be said of gallstones and its train of gastric symptoms, and we are all familiar with the frequent finding of evidence of stone or inflammation in the gall bladder when the abdomen is opened for other and more obvious reasons. Again, chronic obliterative appendicitis may never offer an opportunity for diagnosis but may lead to a train of symptoms which may readily be attributed to hyperesthesia of the nervous system.

Persistent localized pain in the abdomen should never be diagnosticated as nerves without a complete examination, including exploration, if such exploration will not militate against the patient's general condition, as we have all seen cases who were much relieved when they were authoritatively assured that no pathological change existed in the abdomen. The advance in surgical technique has placed us in a position where we may recommend it to patients with confidence as having, *per se*, no unfavorable aspects.

There are two other sets of cases in which operation is debatable, and in which numerous conditions peculiar to each case render almost impossible any general rule as to surgical procedure. I refer to exophthalmic goiter, and to that large class of cases whose name ends in ptosis.

In regarding exophthalmic goiter as a nervous disease there is doubtless an opportunity for an exception, but in so many cases the nervous symptoms associated with this disease predominate that clinically it may be so considered. The operative treatment is fraught with so many and so grave dangers that its study has brought forth some remarkable statements. The methods of Kocher of Berne to avoid the dangers of the administration of an anesthetic; the mortality in very skilful hands; the endeavor to remove the dangers of anesthesia by repeated etherization, and some of the disadvantageous postoperative results are but a few of the many factors to be considered in the surgical aspect of the disease. Since the introduction of the Rodgers-Beebe serum many cases which showed no improvement under medical care have been cured, and many also improved, so that it would seem that in the cases where this treatment is available and appropriate it should be chosen before surgical interference; but there are, however, a large number of cases still remaining which demand surgical treatment if anything is to be done for the sufferers from this disease. These cases may be grouped for brevity as follows: (1) Those in which serum treatment or other medical treatment has proved unavailing. (2) Those in which the above treatment is not applicable, either because it does not act, or when the activity of the disease renders such a slow method impossible to the patient. (3) Those cases in which the thyroid gland has become so enlarged that pressure is exerted to an alarming extent on the trachea and esophagus.

In these three groups of cases it seems that surgery is imperative and many of the radical cures are so complete and offer such a good prospect of renewed and continued health that surgical treatment would seem to claim a larger number of adherents in the future.

That very large group of cases in which nervous symptoms predominate, which result in or are concomitant with the displacement of abdominal viscera, has afforded a wide field for surgical endeavor, and yet the results, even with the best of methods and in the most skilled hands, have not been uniformly satisfactory. In general it may be said that the surgical operation, though it tends to restore a more nearly normal relation to the abdominal viscus, which is the point of operation, never succeeds in completely remedying the condition, but places that viscus in its place to be there maintained by cicatricial or by other means; and, further, while one organ may be so treated, the other viscera may be in a condition of partial prolapse and it is not possible to sew fast all the contents of the abdomen.

There is, however, another aspect, and that is that many symptoms may be entirely relieved and some greatly ameliorated by the suitable employment of fixation operations. The best results are those seen after operations on the uterus and its adnexa, and in the great majority of cases where these organs are the only ones displaced it would appear that they may be maintained in a normal position and cause no further trouble to the patient.

The movable kidney with its train of symptoms

has been the seat of operation very numerous times, and the records are copious enough to possess considerable value. There is, of course, no question that operation is advisable when symptoms referable to the kidney itself intervene, as hydronephrosis, but the weight of surgical opinion inclines to the operation of nephropexy when only intestinal symptoms are present or when Dietel's crisis make their appearance. The results are on the whole favorable, and the condition being one which involves little danger, the fear of minute cysts in the kidney surface as a result of the sewing being negible, should be recommended for operation when the kidney alone is movable.

In general splanchnoptosis there is little question of surgical operation, but in the few cases of hepatopexy that have been followed for a sufficient time, it seems that the results are not unfavorable. The various operations for gastropexy have on the whole been unsatisfactory so far as relief of symptoms is concerned, though anatomically successful.

Cases Harmed by Operation.—To what extent are patients harmed by operation? Many claim to have been made nervous wrecks by operation, but a careful analysis of these cases will show that those precautions mentioned earlier in this paper in regard to the preoperative and postoperative care have either been neglected or slighted or that the patient never was given or never took a chance to recover fully from the operative procedure superadded to the preexisting nervous insufficiency.

Those rare cases which may be said to have the operation habit exhibit the antithesis of the last group, but present almost the same symptoms, and are eager to persuade the surgeon to perform radical operations for the most trivial complaints. It will be seen from the foregoing that the attitude of the surgeon to such nervous cases is practically that toward any patient whether suffering from any nervous complaint or not, but that he must regard his surgical activity as but an incident—however essential it is—in the general treatment of the patient. There is, however, one class or type in which operation should be avoided unless absolutely imperative. This group may not readily be defined. They were "delicate" children, have been nervous or hysterical for years, always looking for sympathy, dependent mentally and physically, and feeling no gratitude for whatever may have been done for them. Many of this type, generally young women, have had various viscera removed or readjusted, and if they do not make the surgeon the object of litigation, they at least blame him for their continued invalidism.

In all cases where there is even a remote doubt as to the diagnosis of where there is any uncertainty as to the benefit accruing to the patient from operation, the opinion of careful medical and nervous expert diagnosticians should be obtained to determine so far as possible the exact physical and nervous potentialities of the patient.

In conclusion we would suggest:

I. Greater care in the diagnosis of nervous affections.

II. More rigid investigation of possible associated medical diseases.

III. Exact determination, if possible, of the association or disassociation of the nervous part and physical part of the disease.

IV. Reconsideration of operation in all cases.

V. The appreciation of the profound effect of surgical diseases on the mental system.

VI. The necessity of treating the nervous condition before and after the surgical disease has been eliminated.

VII. The careful avoidance of operation where it can do no good or where it may result in positive harm to the patient's nervous system.

GONOCOCCUS INFECTION OF THE KIDNEY WITH REPORTS OF CASES.*

By FRANCIS R. HAGNER, M.D.,

WASHINGTON, D. C.

PROFESSOR OF GENITOURINARY SURGERY, GEORGE WASHINGTON UNIVERSITY, ATTENDING GENITOURINARY SURGEON, GEORGE WASHINGTON UNIVERSITY HOSPITAL AND GARFIELD MEMORIAL HOSPITAL.

A CASE of pyelitis in which a pure culture of the gonococcus was obtained which came under my care during the past winter suggested that a review of the literature of this subject might be interesting. I shall only consider the cases caused by the gonococcus alone. Careful search of the literature discloses some sixteen cases of mixed infections in which the gonococcus was thought to be present, and only nine cases could be found in which the gonococcus as the causative agent alone was demonstrated. The character of the infection in some of these nine cases can be questioned as no cultures were taken.

There is a diversity of opinion as to whether the infection is an ascending, hematogenous, or lymphogenous one. From what I can learn it seems more than probable that in the majority of cases it is an ascending infection due to extension along the lymphatic vessels surrounding the ureters, as it has been shown by Albarran that an intimate relation exists between the lymphatics supplying the posterior urethra, bladder, and kidney. Dowd (MEDICAL RECORD, June 25, 1898) in discussing the infrequent recognition of gonorrheal pyelitis, says: "The misleading point has been in assuming that the inflammation of the bladder must precede the involvement of the kidney pelvis. I have in a number of cases found the bladder free from any involvement, the cystoscope showing only one or two reddish streaks, apparently under the mucous membrane, extending from the urethral to the ureteral openings. The condition appeared to be extension by lymphatics, and not by continuity." Israel, Ebstein, and others report cases in which ascending pyelonephritis was not preceded by indications of active cystitis, etc.; on the contrary, the bladder seemed to be quite free from involvement. I cite this, as in my case there was no evidence of cystitis being present except an increased reddening of the trigone and especially the right ureteral orifice.

Watson and Cunningham, in their text book, give in the following order the organisms that cause renal infection and suppuration, the colon, staphylococcus, streptococcus, proteus vulgaris, pneumococcus, typhoid bacillus, and the gonococcus. From this it is seen that these gentlemen consider it as the *rara avis* in pyelitis. It seems to be the opinion of most authorities that the gonococcus prepares the soil for other organisms by lowering the resistance of the tissues, which is probably true, but I believe that a more thorough examination of the urine from the separate kidneys in cases of chronic pyuria associated with chronic gonorrhea will lead to a more frequent demonstration of the gonococcus alone as the causative agent in pyelitis.

*Read before the American Association of Genitourinary Surgeons at Washington, D. C., May 3, 1910.

The amount of destruction in the kidney structure possibly depends in a great measure upon the length of time the disease has persisted and possibly whether the infection has taken place first in the pelvis or in the cortical portion of the kidney. The case reported by Dr. Bransford Lewis had possibly lasted twelve years, as during all this time the man had purulent urine and symptoms in the affected kidney. Here there was an interstitial nephritis with numerous suppurating cavities that from the pathological findings had unquestionably been present for a long time. It is more than probable that if these cases were diagnosed early and appropriate treatment instituted, such a condition as total destruction of the kidney would be prevented.

Dr. H. H. Young of Baltimore reports a case occurring in 1897 in which the patient suffered with retention of urine, cystitis, and double pyelitis. The urine obtained from the bladder by suprapubic puncture showed gonococci in cover slip and cultures, no other organism being demonstrated. No catheterization of the ureters was done, but Dr. Young argues that the gonococcus was the cause of the pyelitis, for if it had been caused by any other organism it would have been demonstrated in the urine obtained from the bladder.

Dr. Young feels that this is the first case in which the gonococcus was demonstrated as causing pyelitis. The final outcome of this case is unknown, as the patient refused operation and left the hospital.

In Casper's first case the patient had contracted gonorrhea seven months before the irrigation of the pelvis was begun. Here the capacity of the renal pelvis was 100 c.c., showing considerable dilatation of the renal pelvis. This case was treated twice during the first week, then once a week. Three weeks after the first irrigation the urine was clear and no gonococci were found. A sudden recurrence took place, numerous pus cells reappeared with intracellular gonococci. After a subsequent recurrence the condition finally cleared up. It seems to me that with a pelvis of this capacity that it is more than probable that the kidney structure itself would be more affected than in those cases that have a more nearly normal pelvic capacity and would possibly account for the numerous recurrences noted.

In Casper's second case the diagnosis was made on July 30, 1901, and the treatment, consisting of irrigation of the renal pelvis, was not started until five weeks later. In this case the capacity of the renal pelvis was 25 c.c. Five days later the urine was clear and the patient appeared well. There were four subsequent renal irrigations, and two months after the last irrigation the patient's urine was still free from pus.

Dr. Bransford Lewis, in his most interesting case of three ureters with one infected by the gonococcus, also treated by lavage. He says that the urine quickly became clear and the patient left for home within a week, there being no recurrence of the purulent urine.

The second case reported by Sellei and Unterberg was a pure gonococcus infection, cultures showing typical Gram negative gonococci. The pelvis of the kidney here was of normal capacity, holding 10 c.c. of fluid. This case promptly recovered under pelvic lavage.

Weiswange, in 1908, reported a case occurring seven days after confinement. Many gonococci were found in the urinary sediment, the patient had had no gonorrhea for six years. She improved and was discharged. Some time later she returned. A nephrotomy was done and pus evacuated from the upper pole of the kidney, the abscess cavity extending into the pelvis. It would seem from a study of these cases that the earlier the diagnosis the more effectual the lavage of the kidney.

Of these nine cases of gonococcus infection of the kidneys, one refused treatment, the outcome being unknown, three were not discovered until post mortem, one was subjected to nephrotomy with recovery, and the remaining four, treated by pelvic lavage, also recovered.

From an analysis of these cases it would seem that pelvic lavage has a place in the treatment of this form of pyelitis. Of course, where there is great destruction of kidney structure, as in the cases reported by Dr. Bransford Lewis and Dr. Weiswange, it is inconceivable that this treatment could be beneficial. We feel that an idea of the amount of kidney destruction that has taken place can be determined quite accurately by filling the pelvis through the ureteral catheter with argyrol and radiographing the kidney. If the outline of the kidney pelvis approaches normal, renal lavage should afford a favorable prognosis. It might be advisable also to use the gonococcus bacterin, as was done in my own case. Of course, if the disease has persisted for a long time, as evidenced by the distortion of the kidney pelvis, the question of nephrotomy or nephrectomy should be considered.

The following is a report of my own case:

The patient, a male, aged 35, first consulted me on September 20, 1909, being referred by Dr. Dillenback, complaining of a profuse urethral discharge and right inguinal pain radiating to the back and to the region of the right kidney, the character of the pain being described as nagging and more or less persistent. He had gonorrhea ten years before, mild in character and recovering promptly. His present attack of gonorrhea began six weeks before with a very profuse thick discharge and the typical symptoms of this malady. Five days previously pain began in the right inguinal region along the right ureter of the kidney, a nagging, more or less persistent, pain, but not unbearable, worse at night and seeming to be aggravated when in the recumbent posture. His temperature had ranged from 99 to 100° for three or four days. He had no perineal pain, no pain on the left side, but some burning on urination. The daily urination was not markedly increased in frequency; nocturnal urination occurred once every four hours. He had no chills, no nausea and no hematuria.

On examination a profuse purulent urethral discharge was noticed, the penis was very much swollen and great periurethral infiltration extending along the pendulous and bulbous urethra was observed. Examination of the prostate revealed a very hard somewhat enlarged gland. Both seminal vesicles were enlarged and infiltrated, the right being the one most affected and the ampulla of the right vesicle being hard and nodular. From this very clear history I should have suspected pyelitis. I considered his pains were due to the greatly enlarged right seminal vesicle, and suggested hot normal salt rectal irrigations. This apparently relieved his pain, and he felt much more comfortable. He returned in ten days, his pain having disappeared, but the profuse urethral discharge continued. Rectal examination showed the seminal vesicle less enlarged and the prostate less hard and tender.

I treated this patient from October 1 to November 17, by which time his urethral discharge had entirely ceased, the infiltration of his vesicles and prostate had disappeared, but his urine continued to be filled with pus, although the patient suffered no inconvenience from any vesicle or urethral irritation. He was losing flesh and anemia was beginning to manifest itself. I suggested the advisability of cystoscopic examination and possible ureteral catheterization, as the urethra and adnexa did not account for the amount of pus present in his urine. The patient was cystoscoped at Garfield Memorial Hospital Nov. 17. The bladder capacity was 300 c.c. The bladder mucosa appeared normal, except in the region of the trigone, where it was reddened and the blood vessels congested. This condition was present to a marked degree in the region of the right ureter, the mucous membrane on this side being much more infiltrated than on the opposite side. Wormlike masses of thick purulent material were seen escaping from the right ureter. A double catheterizing cystoscope was introduced and both ureters catheterized. Both catheters were passed without difficulty well up the ureters about 30 cm. The urine from the left ureter was normal and was secreted in a normal manner. From the right there was no secretion for some minutes, then suddenly large masses of thick purulent urine flowed through the ureteral catheter. About 10 c.c. of this purulent urine, acid in reaction, was collected and sent to Dr. Wilkinson for examination. Cover slips showed numerous intracellular diplococci that decolorized by Gram's, cultures were taken on human blood serum agar and the ordinary laboratory media. At the end of thirty-six hours small white colonies were noted on the human blood serum agar that showed typical diplococci, morphologically identical with gonococci, that decolorized by Gram's. This organism was carried through three generations and refused to grow on a fourth transplantation. Cultures taken at the same time on agar, potato and gelatin remained sterile. The secretion from this kidney was so purulent that the advisability of nephrotomy was considered. It was thought advisable to ascertain the size and shape of the kidney pelvis. This was done by filling the pelvis with 50 per cent. argyrol solution. As soon as 10 c.c. had been injected into the kidney the patient complained of pain and fullness in the region of the right kidney. A radiograph was immediately taken and showed a practically normal pelvis.

At the end of two days the ureter was again catheterized and purulent urine obtained that showed the gonococci in cover slip. The kidney pelvis was then washed with two ounces of 25 per cent. argyrol. At the end of twenty-four hours the argyrol discoloration had disappeared and the urine appeared a little less purulent. Three days later the pelvis was washed with 1 per cent. silver nitrate. At the end of twelve hours the urine was a little more purulent than before using the silver nitrate, but at the end of thirty-six hours the urine passed was clearer than ever. There were four subsequent washings of the kidney pelvis with 1 per cent. silver nitrate. Immediately following the silver nitrate washings there would be a slightly increased amount of pus for twenty-four hours. An examination twenty-four hours after the last washing showed urine free from pus. As soon as the kidney condition was diagnosed I began giving the patient bacterin, beginning with thirty million and increasing it to fifty million. Whether the improvement will be attributed to the bacterin or the renal lavage I will not attempt to say, but now, nearly five months after treatment was discontinued, the patient is well and his urine is free from pus.

Personally I cannot help but feel that where a kidney pelvis is not greatly enlarged and a radiograph shows a practically normal shaped pelvis and pyelitis is present, we are justified in trying pelvic lavage.

Summaries of cases previously reported:

Friedrich Neuendorff (1892. Zur Frage von dem Vorkommen einer specifisch gonorrhoischen Pyelitis. Dss. Berlin) states that in 1883 Bockhardt injected a pure culture of gonococci into the healthy urethra of a man suffering from dementia paralytica. The patient died a few days later and the pus from the perinephritic abscesses was found to contain an unusually large number of gonococci, and the author (B.) assumed that he had to deal with a specific gonorrheal pyelitis. Since then many writers have expressed doubt as to whether Bockhardt used a pure gonococci culture. Neuendorff reports a case which he believes to have been due to gonococci. He found the organisms in the urine as it was taken from the bladder, not obtained by catheterization of the ureters.

Shinjiro Asahara (1898. Ueber Metastasen der Gonorrhee. Diss. Berlin) reports several cases of mixed infection of the kidney and other organs, demonstrated post mortem. He reports one case of pure gonococcus infection: A servant girl, aged 16, was admitted to Moabit Hospital in Berlin, June 22, 1897. She was unconscious when admitted. The diagnosis was peritonitis, appendicitis, sepsis. She died June 25. Anatomic diagnosis: Septicemia. The cause could not be found at first. The pus from a renal abscess was examined microscopically and found to contain diplococci only; these were recognized to be gonococci. Suitable media was not at hand, and hence no cultures were obtained, as the organisms failed to develop on the media used. Gonococci were also found in the lungs. All metastatic areas examined microscopically revealed gonococci only, no other organisms being found.

Bransford Lewis (*Journal of Cutaneous and Genito-Urinary Diseases*, v. 18, Sept., 1900, pp. 395-404; also *Physician and Surgeon*, Lond., v. 1, p. 167) reports a male, aged 54, single, laborer, admitted in a state resembling uremic intoxication in which he remained till death six days later. Denied ever having gonorrhea or syphilis. He first noted dull pain in the region of the kidneys twelve years ago; there had been gradually increasing lassitude, headache, vertigo, failing vision, anemia, indigestion, insomnia and loss of flesh. Malarial organisms were found in the blood. Urine: sp. gr. 1014, alkaline, but large amount of albumin; there was a heavy, milk-like deposit containing epithelial cells undergoing fatty and granular degeneration, epithelial casts, leucocytes, and triple phosphate crystals. Ante-mortem diagnosis: Chronic parenchymatous nephritis and malarial intoxication. Treatment: quinine, stimulants, and diuretics. No improvement; death. The right kidney was found to contain suppurating cavities, mostly about the size of a walnut. The infection came from the pelvis and collecting tubules, from there spreading to the intermediary zone and gradually absorbing the excretory structures, while the secretory portion suffered indirectly. The ureter also contained pus, and was thickened and dilated. Microscopical examination of the pus showed gonococcus organisms.

Inoculations resulted in obtaining pure cultures of the organisms.

Bernhard Marcuse (*Monatsberichte f. Urologie*, Berlin, 1902, v. 7, pp. 127-190) reports a male, aged 25, who contracted gonorrhea two years previously which was completely cured; second infection occurred in Sept., 1900, associated with cystitis. Internal and local treatment relieved the symptoms, but the urine remained cloudy from pus. While in Berlin in Dec., 1900, some one made a cystoscopy, diagnosing pyelitis of the right side. The right renal region was sensitive to pressure. The patient came to see Dr. Casper April 22, 1901. Cystoscopy with ureteral catheterization of the right ureter showed cloudy urine, pus cells in sediment, red cells in epithelium. The pus cells contained abundant intracellular gonococci of typical form, size and arrangement. The urine from the left ureter was normal. The kidney was treated with lavage of the pelvis twice during the first week, then once a week. On other days irrigation of the bladder and Guyon's instillation of the urethra were made. There was a favorable course. Several weeks after the first irrigation the urine was clear and no gonococci were found, when sudden recurrence took place; numerous pus cells reappeared with intracellular gonococci. Irrigations were renewed, and after a subsequent recurrence the condition finally cleared up. At the last pelvic lavage, in the beginning of August, 1901, the bacteria had disappeared. The patient was lost sight of. (The renal pelvis of the infected kidney had a capacity of 100 c.cm.)

Case 2. About the same time as above case there came to treatment a man, aged 23, with gonorrhoic pyelitis, who had had a soft ulcer and balanitis a year before. He contracted gonorrhea for the first time on May 5, and was treated at once with injections and sandal oil; ten days later there was pain in the region of both kidneys, with fever and symptoms of cystitis; bladder irrigations were made. He was treated by Diday's irrigations since June; micturition became less frequent and painful; the discharge stopped, but the urine was sometimes clear, at other times cloudy. Cystoscopy was done on July 30, 1901. Suppurating urine was obtained from the right ureter, containing numerous pus cells, some red cells, and epithelium, no casts and very little albumin. The pus cells contained numerous typical intracellular gonococci. The left ureter showed normal urine. Vesical irrigations were made only for a while. On Sept. 4, 1901, the first irrigation of renal pelvis with silver solution was made. Capacity of the renal pelvis was 25 c.c. Five days later the urine was clear, the patient felt well, and there was no fever. Sept. 11, 17 and 21 renal irrigations and vesical irrigation were made on alternate days. The urine was clear. On Oct. 28 and Nov. 21 examination showed that the urine had remained clear.

Bransford Lewis, 1906. Three ureters demonstrated during life; ureter-catherization, giving three different urines, one infected with gonococci. MED. REC., N. Y., Oct. 6.

Male, aged 24, was seen Feb. 3, 1906. Repeated recurrence of urethral gonorrhea since 1900, in spite of the employment of all known measures of treatment. When Lewis got the case he discovered three ureters, two on the left, one on the right side. The urines draining from the ureters bore no relation to each other. The urine coming from the ureter at the extreme left had sp. gr. 1005, was quite cloudy, with flocculi floating in it, while the other was more like normal urine. The urine from the extreme left ureter showed much pus and a moderate number of blood cells and epithelium. In a number of the pus cells colonies of diplococci that gave the customary appearance of gonococci to the positive methylene blue stain and decolorized after Gram's stain were found.

In the urine from the middle opening no pus cells and no organisms were found.

A colored silver solution was injected into the left catheter, the pelvis receiving about three drams without causing pain or reaction. The other catheter continued to drain unchanged; evidence of the total independence of the two sources of urine. The right kidney was not affected.

Two days later the infected ureter was again washed with the silver solution. "The silver irrigations of the infected pelvis brought the result desired. Evidences of infection that, up to that time, were persistent almost immediately disappeared, and the urine as quickly became clear. The patient left for home within a week afterward. Dr. Crook and the patient both write that there has been no recurrence of the trouble, although treatment has now been discontinued for over seven months."

Josef Seilei and Hugo Unterberg (1907, *Berliner klinische Wochenschrift*, 1907, v. 44, pp. 1113-1115, report five cases of gonococcic infection of the kidney observed in Budapest. The first case was one of mixed infection by long colon bacilli, diplococci, very thick, and gonococci. The fourth and fifth cases showed colon bacilli only. The third case was also a mixed infection: staphylococci, pseudodiphtheria bacilli, and gonococcoid bacilli. The second case was pure gonococcic infection: J. R., ailing for ten months with urethritis, prostatitis, and cystitis gonorrica. The cystitis had not improved under the usual methods of treatment. Pyelitis was suspected. The left kidney region was sensitive to pressure. The right ureter was catheterized. The urine was cloudy and contained albumin. The sediment contained red cells, much detritus, and a few epithelial cells. Bacteriologically there were a very few diplococci, which were negative to Gram's stain. Cultures on Thalmann-Agar developed typical gonococcus colonies. The authors state that gonorrheal pyelitis is usually cured by rest and internal medication. Direct local treatment is advised in certain cases only, namely, those where internal medication has failed. Irrigation of the renal pelvis is then indicated. They injected from 6 to 10 c.c of a boric acid solution and a 1-1000 silver solution with good results. They also employed collargol in 1 and 2 per cent. solution with like results. The injections were repeated once or twice a week. Several irrigations usually suffice to destroy the gonococcus. They injected from 5 to 10 c.c., allowing the solution to run out, and then injected some more. They used 5 c.c. with the first injection and successively increased the quantity till the patient experienced a sense of tension in the region of the kidney. In no case did they inject more than 10 c.c. at one time. All the cases recovered.

Weisswange (*Münchener medizinische Wochenschrift*, 1908, v. 55, No. 16, p. 967) reports a woman, aged 34, who developed fever, high pulse, and pain on right side seven days after confinement. Leucocytes, casts, and many gonococci were found in the urinary sediment. She was given medical treatment and improved to such an extent that she was dismissed. Some time dater the symptoms reappeared. The right kidney was exposed; an ab-

scess was made out in the upper portion extending into the kidney pelvis. An incision was made; numerous gonococci were found in the pus. Nephrotomy was done and recovery followed. She had not had gonorrhea for six years.

The Farragut, 17th and I Streets.

REPORT OF A CASE OF CARCINOMA OF THE SPLENIC FLEXURE OF THE COLON TREATED WITH THE NEOFORMANS VACCINE.*

By CHARLES D. AARON, M.D., Sc.D.,

DETROIT, MICH.

PROFESSOR OF DISEASES OF THE STOMACH AND INTESTINES IN THE DETROIT POST-GRADUATE SCHOOL OF MEDICINE; CLINICAL PROFESSOR OF GASTROENTEROLOGY IN THE DETROIT COLLEGE OF MEDICINE; CONSULTING GASTROENTEROLOGIST TO HARPER HOSPITAL, ETC.

The case I wish to report is of interest, for the reason that the results seem to have been better than reports of similar cases treated by the neoformans vaccine. The patient, male, aged 55, consulted me February 25, 1910, for stomach trouble. He had been sick for one year, had lost thirty-five pounds in weight, complained of loss of appetite, distress after meals, food would increase the disturbance in his stomach, had both eructations and flatulence, complained much of constipation. He was markedly cachectic. By palpation a mass was easily mapped out in the left side of the abdomen. It was round, immovable and painful on pressure. There was evidence of an incision which the patient said was the result of an operation August, 1909. He could give me no account of the operation.

An examination of the stomach contents showed that he suffered from hyperchlorhydria. There was occult blood in his feces. Inasmuch as I was anxious to know about the incision made last August, I wrote Dr. Russell Caffery of San Antonio, Texas, the surgeon who performed the operation, to enlighten me as to the character of the growth. In his reply, March 19, 1910, he stated that he had discovered what he considered to be a carcinoma of the splenic flexure of the colon. Beyond separating some adhesions nothing was done, for he regarded the case as being inoperable.

Patient entered Harper Hospital, Detroit, March 20, 1910. On account of his extreme weakness he had to be taken there in the ambulance. Owing to the severe pain in the abdomen he was taking on an average of one grain of morphine daily in divided doses. His urine gave a specific gravity of 1018, no albumin, contained numerous hyaline casts, squamous epithelia, small round epithelia, and numerous pus cells. His temperature ranged from normal to 102°, running an irregular course. On the giving of an alkali for his hyperchlorhydria his stomach symptoms soon subsided. In view of his weakness and anemia, hemoglobin 30 per cent., he was given twice daily in the gluteal region: Citrate of iron, .05 gm.; glycerophosphate of sodium, .20 gm.; metarsin bisodic, .10 gm.; formate of sodium, .15 gm.; strychnine, .001 gm. he pains continued severe, there was no desire for food, and he had to be kept under the influence of morphine. It was now that I began the use of the neoformans vaccine. On the morning of March 24, 100,000,000 neoformans vaccine was given subcutaneously in the abdomen. He slept the greater part of the afternoon. The next day he was able to take more nourishment than usual. No morphine had to be administered for pains. The opsonic index was not taken at any time. The giving of the neoformans vaccine depended in the main upon the clinical symptoms. March 28, four days from the giving of the first inoculation, another 100,000,000 of the vaccine was given. The patient continued to feel better, his appetite improved, and his bowels were more nearly normal. The pain was constantly decreasing, and to my surprise the induration on the left side of the abdomen seemed to be rapidly subsiding. The vaccine was given: April 4, 150,000,000 neoformans vaccine; April 8, 150,000,000; April 11, 150,000,000. The patient from now on was able to walk around the hospital and began going out doors. April 13, 50,000,000 neoformans vaccine; April 15, 50,000,000; April 16, 50,000,000. The patient continued to improve so steadily that on April 16 he was sent home to his family physician, Dr. C. A. Cobb, to continue the treatment.

Upon his arrival home Dr. Cobb wrote that he was surprised to find the tumor gone. The patient complained of some pain and discomfort at the site of the old tumor, but the physician could feel nothing.

May 14, 1910, Dr. Cobb wrote: "Our patient is still improving. About the sixth of the month he began to have pain and uneasiness in left side (site of old growth). Upon your advice I gave him 150,000,000 neoformans vaccine at one dose. The following day, as the pain was no better, and as he showed no depression from previous injection, I repeated the same dose. The following day the pain persisted and I repeated again the 150,000,000 neoformans vaccine. That afternoon the pain vanished and has not returned since." His letter further states: "I am unable to detect any signs of a growth or nodule. His general condition continues to improve, he eats well, sleeps well, takes some exercise, and is gaining in weight. Last week I attended the State Medical Association and met Dr. Caffery of San Antonio. He said that at the aforementioned operation, when he had opened the patient's abdomen he had found a growth the size of an orange involving the splenic flexure of the colon. To remove this would have necessitated resection of at least eight inches of gut. There was a general infiltration of the retroperitoneal glands and adjacent structures. He was greatly interested to learn of the improvement from the use of neoformans vaccine."

May 27, 1910, Dr. Cobb writes he is able to find by palpation a small nodule the size of a hazel nut at the site of the old growth. He says it does not seem to have grown any larger in the past week. The patient does not care to exercise, as it hurts his side. He is eating well and gaining all the time. He was given 200,000,000 neoformans vaccine.

May 30, 1910, the doctor writes that there was a marked reaction after the last inoculation. A temperature of 103° F., which after six hours declined to normal. There was not such a reaction after any of the other inoculations of 150,000,000. The nodule cannot now be felt by the most careful continuous palpation. The patient's general condition continues good.

On May 28, 1910, the urine was markedly alkaline, specific gravity 1.023, trace of albumin, numerous pus cells, numerous blood cells, and hyaline casts.

The report of the blood findings during our observation is as follows:

*Read at the annual meeting of the American Gastro-enterological Association, St. Louis, June 6 and 7, 1910.

HARPER'S HOSPITAL LABORATORY.

Blood test March 21, 1910: erythrocytes, 1,980,000; hemoglobin, 30 per cent.; color index, .75; leucocytes, 8,600.

Differential white count: polymorphonuclears, 83 per cent.; large lymphocytes, 3 per cent.; small lymphocytes, 13 per cent.; eosinophiles, 1 per cent. The red cells show some poikilocytosis. They stain unevenly. An occasional erythroblast was seen.

April 6, 1910: Erythrocytes, 2,590,000; hemoglobin, 32 per cent.; color index, 0.6.

Differential white count: polymorphonuclears, 60 per cent.; large lymphocytes, 4 per cent.; small lymphocytes, 36 per cent.; eosinophiles, 1 per cent. The red cells show variation in size and shape and staining reaction. A few nucleated reds were found. The leucocytes are increased in number.

Laboratory of Drs. Wier & Thomson, Beaumont, Texas. Dr. Cobb. April 23, 1910: hemoblogin, 70 per cent.; red blood cells (4,788,000), 95 per cent.; color index, .73; leucocytes (13,000), 162 per cent.

Differential white count: Large lymphocytes (500), 4 per cent.; small lymphocytes, 35 per cent.; polymorphonuclears, 56 per cent.; eosinophiles, 4 per cent.; gasophiles, 5 per cent.; transitional, 0.

Dr. C. A. Cobb: The blood findings in this case are certainly not consistent with his general appearance. The anemia, judging from the blood picture, is due more to a loss of coloring than to the red cells, *per se;* the color index is quite low. There is a slight leucocytosis (13,000) but the eosinophiles are the only cells increased beyond their normal percentage. This picture, however, is consistent with Da Costa's description of the blood in malignancy. Yours very truly, Thomson.

May 11, 1910: Hemoglobin, 70 per cent.; red blood cells (3,496,496), 69.93 per cent.; color index, 1; leucocytes (15,000), 187.50 per cent.

Differential white count: Large lymphocytes, 5.5 per cent.; small lymphocytes, 33 per cent.; polymorphonuclears, 57.5 per cent.; eosinophiles, 4.5 per cent.

May 28, 1910: Hemoglobin, 70 per cent.; red blood cells (4,208,000), 84 per cent.; color index, .83; leucocytes (16,000), 200 per cent.; plasmodium malariæ, none.

Differential white count: Large lymphocytes, 6 per cent.; small lymphocytes, 24 per cent.; polymorphonuclears, 68 per cent.; eosinophiles, 2 per cent.; basophiles, 0; transitional, 0. No nucleated reds, no poikilocytes—even staining.

It is too early to determine the outcome of the case. To me it is interesting because of the relief of the painful symptoms, the rapid disappearance of the tumor, and the marked improvement in the general condition of the patient—an improvement which he has maintained up to the present time.

It was in 1902 that Doyen called attention to the *Micrococcus neoformans* which he found in cancerous tissue. At first he thought he had found the specific cause of cancer.

Karwacki (*Warschauer med. Woch.* 1906, No. 5) comes to the following conclusions after his use of neoformans vaccine: (1) the neoformans vaccine may induce the involution of tumors. (2) The vaccine acts upon epithelial growths while sarcoma remains uninfluenced. (3) In the presence of metastases, marked degeneration of the glands and cachexia, it should not be used. (4) The prognosis should be given with care and only after long observation. (5) The neoformans vaccine can be used alone or assisted by surgical measures.

I appreciate that the report of this case is an early one and I shall expect to say more about the case next year.

NOTE.—September 10, 1910. The improvement of the patient was a temporary one. He went to Rochester, Minn., for consultation June 15, 1910. Operation by Dr. W. J. Mayo, June 25, 1910, disclosed advanced carcinoma of splenic flexure. Died July 2, 1910. The autopsy findings by B. C. Willis were as follows:

"Body that of a large, poorly nourished and anemic man, ankles slightly edematous. Large incision with drainage tube in lower quadrant of left rectus, but nothing drained. Another drainage stab wound made in left flank, posterolateral with tube in place, nothing drained. Chest well formed and large. Lungs were distended and did not collapse. Some straw-colored fluid in each pleural cavity, more marked on right side where there had been an old pleurisy of some years' standing. Right lung, lower and middle lobes practically solid, on section it looked like hypostatic pneumonia, heart flabby and somewhat hypertrophied, a little more fluid than usual in the pericardial sac. Abdomen—clean, though intestines were firmly adherent to anterior abdominal wall around incision. Drainage tube was folded upon itself. There were a couple of pus pockets in the mass of tissue around lateral anastomoses of transverse colon with upper portion of rectum. The cecum was distended with gas, and the hepatic flexure was adherent to gall-bladder in such a manner as to pull on ascending colon. The perirenal fat on left side was involved in inflammatory mass. Liver had undergone moderate fatty degeneration. The kidneys showed subacute nephritis grafted upon chronic interstitial nephritis. Spleen and pancreas negative.

"Cause of death—hypostatic pneumonia and pleurisy with effusion; contributory, resection of colon for carcinoma and subacute nephritis.

"The findings at operation: Carcinoma of splenic flexure, advanced. Resection of two-thirds of transverse, splenic flexure, descending colon and half of sigmoid, isoperistaltic anastomosis between the sigmoid, ten inches above the rectum, and hepatic flexure; necessary to do extensive separating operation of the stomach—anastomosis sutured to abdominl wound. Peritoneum joined so as to throw the bed from which the tumor of bowel was removed outside of peritoneal cavity, end of bowel turned in. Line of anastomosis wrapped with omentum. Split rubber tube, two strips gauze through stab wound, left side.

"Pathological findings—tumor of intestines, carcinoma (adeno)."

32 WEST ADAM'S AVENUE.

THE DIAGNOSIS OF INCIPIENT PULMONARY TUBERCULOSIS.*

BY HENRY HUBBARD PELTON, A.M., M.D.,

NEW YORK.

ADJUNCT ASSISTANT ATTENDING PHYSICIAN TO BELLEVUE HOSPITAL; CHIEF OF THE MEDICAL CLINIC, PRESBYTERIAN HOSPITAL, OUT-PATIENT DEPARTMENT.

OF the problems which confront the physician today none is more important and interesting than the diagnosis of incipient pulmonary tuberculosis.

*Read before the New York Society of Medical Inspectors, May 10, 1910.

The chances for recovery of a tuberculous patient are in most instances, if not in all, in direct ratio to the earliness of the discovery of his disease; this fact alone should be a sufficient argument in favor of the employment of every means toward the detection of the affection in its earliest form. The importance, again, of diagnosis in the first stages of infection cannot be overrated from the point of view of social economy; it is costing the municipality and the State thousands of dollars yearly to care for subjects in the advanced stages of the disease, who, had their affection been diagnosticated in its incipiency, might be supporting themselves.

A discussion of the economic aspect of the question is outside the scope of this paper, but a consideration of the number of tuberculosis patients in our hospitals and other institutions whose support is derived wholly or in part from the public funds or from private charity is appalling; likewise the number of families which, because their older members are unable to exercise their earning power on account of tuberculous disease, receive aid from the community is no small one.

For the early diagnosis of pulmonary tuberculosis no unusual training is requred; it is wholly within the attainment of the general practitioner who will use his powers to their full. And it is fortunate that this is so for most of the patients to whom this diagnosis is pregnant with importance apply, first, at least, to the class of physician who has come to be termed the "family doctor." There are, now and then, naturally enough, cases which present unusual difficulties but these are few among many. In the diagnosis of incipient pulmonary tuberculosis, as in that of any other disease, best results will follow a certain routine procedure. Each step in this procedure is of importance and particularly do I wish to emphasize this fact, for the diagnosis of tuberculosis in its early incipiency often cannot be assured until the results of these steps are reviewed and summed up.

1. The History of the Patient.—This should be taken in full and with care; no detail of importance should be neglected. Heredity, to my mind, plays a much less important rôle in the causation of the disease than the fact that the patient may have had intimate association with tuberculous individuals. Such association may have taken place at home or elsewhere, the work-room, for instance. Trades of themselves seem to have no special etiological significance, but in the nature of things the affection is much more likely to attack those who work in crowded, ill-ventilated, and unsanitary quarters than those who are employed under the opposite conditions or in the open air.

The previous history of the patient with regard to former illnesses may teem with helpful facts; for instance, histories of influenza, pleurisy, pneumonia, and even of digestive troubles are often strongly suggestive of tuberculous lung disease. Surgical conditions, such as hip and spinal disease, cervical adenitis and anal fistula point distinctly toward tuberculous infection.

In eliciting the history of the patient's present illness the polymorphous character of the symptoms cited should not in any way be allowed to allay the suspicion of tuberculosis if there is the least reason for such; in fact by far the safest stand for the physician to take is to judge the patient guilty of tuberculous infection until, by every means at the examiner's command, he has been proven innocent of the disease.

Miller[1] gives the following as the more usual initial symptoms: (1) Catarrhal or influenzal manifestations in which the cough is the chief symptom. (2) Symptoms suggestive of malaria in which general malaise, loss of appetite, slight evening rise of temperature, and mild digestve disturbances appear gradually, with or without cough. (3) Hemoptysis. This should always be held to be of tuberculous origin unless other distinct cause can be shown. (4) Gastric disturbances which obscure other symptoms of more definite character. (5) Anemia, without apparent cause. This symptom should not be allowed to deceive the diagnostitian in young girls in whom chlorosis is so frequent. (6) Pleurisy with effusion. This should always be considered tuberculous until the contrary is proven. (7) Pain in the chest. This is a not infrequent initial symptom. It is usually dull and aching in character and often is referred to the shoulderblade. Miller holds that the combination of any two of these symptoms or trains of symptoms should, as a rule, be sufficient evidence to establish a tentative diagnosis. Even where definite physical signs are lacking suspicion should be kept alive and the physician should be stimulated to further careful observation of the patient and to regular and frequently repeated physical examinations. In such cases the time will often come when physical signs of certain diagnostic import will be detected.

2. Physical Examination of the Chest.—As a preliminary, and a most essential one, the patient should be stripped to the waist and seated in a light room of which the temperature is sufficiently high for comfort; he should be taught how to breathe and to cough so that the auscultatory signs may be elicited to the best advantage. The inspection of the chest in incipient cases often offers no evidence of value. The main points on which observation should be centered are (*a*) the shape of the chest; (*b*) its symmetry; (*c*) its movement. One should notice whether both sides of the thorax expand synchronously, whether apices and bases show a correspondingly well-marked expansion, and whether there is abnormality of the general conformation of the chest. The supra and infraclavicular regions are often little retracted until the disease is well advanced. A low chest expansion is of little diagnostic value.

Palpation may reveal changes in vocal fremitus; localized increased fremitus may indicate beginning infiltration or consolidation.

Percussion. Slight deviations from normal pulmonary resonance may be demonstrated, particularly at the apices, but they are often of such ill-defined character as to be of little diagnostic worth when not strengthened by other evidence.

Auscultation is the means which is to be relied on as giving the most valuable diagnostic testimony. Miller[1] states that cases in which one can, with certainty, demonstrate a lesion in the absence of abnormal auscultatory signs are very few. He considers the use of the stethoscope preferable to that of the unaided ear, for with it sounds unappreciable to the latter become plain; râles are more easily heard, and the instrument is better fitted for application to the various regions of the chest. The ear, of course, may be employed alone and aided by the stethoscope. At times the former is more acute in the detection of changes in the breath sounds. The portions of the chest over which abnormal physical signs are more likely to be demonstrated in early infections are: the supraclavicular fossæ; the first

intercostal spaces, particularly at their inner and outer extremities; the region between the scapulæ just below the fourth dorsal vertebra; along the vertebral border of the scapula when the arm is thrown around and in front of the neck with the hand on the opposite shoulder, this area being over the interlobular septum; an area internal to the angle of the scapula; and, in children, the fifth and sixth spaces just external to the nipple. Miller suggests, as an aid to accurate auscultation, the use of a short, sharp cough alternating with a quickly-expelled, short, quick inspiration; this should be employed previously to any deep respiration for the measurement of expansion in order that râles of evanescent character may not fail of detection.

By this method of auscultation the following observations may be made: (1) The character of the breath sounds; (2) the presence of râles and their character; (3) the cough sound. The cough should never be omitted for, in itself, it has a character peculiarly its own; this may show the same variations as the breath sounds, and in addition it is essential for the appreciation of fine râles, which may not be audible at any other time. Also by its use we may be able to detect minute interruptions in continuity which are not true râles, but are analogous to the change in breath sounds described as granular or rude breathing. The presence of this alteration in the respiratory sound indicates an early stage of the condition which later is evidenced by the presence of true râles. Changes in voice sounds may be demonstrated by auscultation. Alteration of the whispered voice tending toward the bronchovesicular quality is evidence of slight consolidation; this change is appreciated more accurately by this sign than by either the true voice or the breath sounds.

The toxemia due to tuberculous infection is evidenced by an extremely important (from a diagnostic standpoint) train of symptoms, the most common of which are slight evening rise of temperature, rapidity of pulse, loss of weight, undue feeling of fatigue, increased rate of respiration, and anemia. These symptoms are of most value to the diagnostician when they are observed for a week or more under different conditions, at different hours of the day and especially before and after exercise. An important early diagnostic sign is a varying pulse rate and temperature. The latter may not rise greatly above the normal but its daily range is likely to be abnormally large. These symptoms and signs of toxemia, when taken in connection with a history pointing toward tuberculous infection, are of extreme diagnostic value even when unassociated with lung changes sufficiently marked to be demonstrable by physical examination.

Sputum Examination.—In incipient pulmonary infections sputum examination is very likely to yield little diagnostic assistance, still it is important that frequent specimens should be examined and, while a positive result assures the diagnosis, repeated negative ones are by no means conclusive. Bacilli are said to be absent from the sputum in quite 65 per cent. of all incipient cases. Recently Paterson[2] has advocated treating the sputum with antiformin, which is a liquid composed of equal parts of liquor sodæ chlorinatæ and 15 per cent. solution of caustic soda, in the following manner: 10 c.c. of sputum are mixed with 2.5 c.c. of antiformin. The mixture is allowed to stand for twenty-four hours, when it is shaken and centrifugalized. The supernatant fluid is then drawn off and replaced with normal sodium chloride solution; this mixture is shaken and centrifugalized and the process is repeated. The sediment is then smeared and stained in the usual manner. He believes this process is a considerable aid in finding bacilli in specimens where they are few in number.

Hausmann,[3] noting that many of his gastric cases gave evidence of beginning lesions at the apices, has examined the contents of their fasting stomachs (provided no sputum was obtainable) and in six cases within two months was able to demonstrate the presence of tubercle bacilli. This suggestion would appear worthy of further study, especially in connection with the use of antiformin and should be particularly applicable in children from whom it is often quite impossible to get specimens of sputum.

The inoculation of guinea pigs with sputum in which bacilli are not demonstrable is of value as a diagnostic help but is rather beyond the resources of the practitioner.

The stools are said to contain the bacillus, even in beginning tuberculosis, and examinations of them may reveal its presence.

Blood Examination.—The statement made by Rosenberger that the blood of incipient cases often contains demonstrable tubercle bacilli is uncorroborated; in fact it is now believed that his results were due to the fact that his wash water was contaminated with an acid-fast bacillus morphologically similar to the tubercle bacillus.

Cytologic Diagnosis.—Widal believes that a preponderance of lymphocytes in the blood speaks for tuberculous infection while a majority of polynuclear leucocytes of neutrophile and eosinophile types excludes the disease, but this theory fails of general acceptance outside of France. The employment of Arneth's method of differentiation of the nuclei of the leucocytes is being found to be of some value in diagnosis, but no definite work along this line has as yet been published.

The Opsonic Index.—King[4] states that certain observations and experiments conducted by him and Inman[5] seem to show that opsonic index determinations may have a practical use in the diagnosis of early tuberculosis. Their complicated technique and the special knowledge necessary for their performance would seem to militate greatly against their general use. For diagnosis the relation of the temperature to the opsonic index before and after periods of exercise is observed. In tuberculous patients the temperature rises after exercise while the opsonic index is lowered. Jacobs[6] finds that the opsonic index rises in pulmonary tuberculosis after a period of deep breathing lasting for about a half hour. He considers that this exercise produces an autoinoculation which results in a corresponding rise in the opsonic index and regards this method of great value in early diagnosis since by it the presence of infection can be demonstrated long before bacilli can be found in the sputum.

Agglutination Tests.—These, according to von Ruck,[7] may be relied on, either in connection with tuberculin tests or alone, to confirm the diagnosis in most nonbacillary cases where the physical signs are suspicious. Of 300 cases tested he found the reaction negative in 20, and in the rest positive in dilutions of from 1 to 5 to 1 to 50. Arloing and Courmont[8] have stated that agglutination in dilutions below 1 to 5 should not be considered diagnostic, but von Ruck believes that in the absence

of other definite diagnostic evidence no reliance should be placed on a dilution less than 1 to 10. When subjective symptoms and physical signs point toward infection he is accustomed to consider a reaction in higher dilution of positive value and that the tuberculin reactions may be dispensed with since their results have always confirmed the serum tests in his experience.

The Tuberculin Tests.—Of these there are four, three of which have been introduced comparatively recently.

1. The Percutaneous Test.—This consists in the inunction of an ointment of equal parts of old tuberculin and lanolin. The site of the inunction is usually a small area of the skin over the abdomen. A positive reaction is evidenced by the appearance of a papular eruption. Bandelier and Roepke[9] believe that this test is inferior in its certainty to the cutaneous test which is uninfluenced by the thickness and dryness of the skin, the number of its pores and various constitutional conditions, factors which materially affect the percutaneous test. The field of the latter is in infants in the first half year of life and in these a positive reaction points strongly toward the probability of an active tuberculous infection.

2. The Conjunctival Test.—This consists in the instillation into the eye of a drop of a ½ to 1 per cent. solution of old tuberculin in normal NaCl. A positive reaction is evidenced by a varying degree of congestion of the caruncle and conjunctiva which appears in from three to forty-eight hours. This test is a reliable test for patent bacillary tuberculosis and as such it is superfluous. It does not show whether the process is active or inactive. A negative reaction does not prove the absence of active tuberculosis and positive reactions may appear in healed tuberculosis, in the clinically nontuberculous, and in the healthy. As a rule the test does not react positively in those immune to tuberculosis or in the cachexias of tuberculosis and other conditions.[9] The disadvantages of the conjunctival test are that it cannot be employed if there is any inflammatory condition present in the eye and that it may cause untoward results. Both it and the percutaneous test are at present generally discarded.

3. The Cutaneous Test.—This consists in the inoculation of a small scarified area of the skin, preferably upon the arm, with a drop or two of a 10 to 25 per cent. solution of crude tuberculin in salt solution (or 5 per cent. carbolic-glycerin, 1 part; normal sodium chloride, 2 parts). A positive reaction is evidenced by the appearance in from twenty-four to forty-eight hours of a zone of light pinkish redness about one-half inch wide and accompanied by swelling; finally a papule forms which disappears in from seven to eight days leaving behind some temporary discoloration of the skin. The advantages of this test are[9] that it is simple, harmless, applicable to febrile and bed patients, and causes no local or constitutional disturbance. A positive result does not point out the site of the lesion, nor show whether the process is active or inactive. It may appear in the clinically nontuberculous and indicates that the body at some time and in some manner has been infected with the tubercle bacillus. Cases in which positive reactions occur and in which no lesion is demonstrable may be accounted for on the ground that the lesion, being insignificant, has been overlooked. A negative reaction points strongly toward freedom from tuberculous disease, but on the other hand the reaction may remain negative in the presence of actually existent and clinically demonstrable tuberculosis. Negative results may occur also in certain constitutional conditions, such as general cachexia, and in idiosyncrasy of the skin or the exanthemata. The positive result is of specifically tuberculous nature and its occurrence points toward pathologically existent tuberculosis.

The great field of usefulness of this test is in children and in them a positive reaction is an evidence strongly in favor of the existence of tuberculosis. In adults a definite and promptly appearing reaction is moderately good testimony in favor of recent and active infection. Mild, delayed, and atypical reactions are valueless in diagnosis since healed foci which have never given definite signs or symptoms may be evidenced by positive reaction. The negative value of the test is impaired to but slight degree by the exceptional cases of tuberculosis which fail to react for the reasons given above.[1]

Baldwin[10] considers the cutaneous test to be the one most suitable for general use, and that it is absolutely harmless. No other test is required for children, because in them a positive reaction is more significant of recent infection and does not often occur in apparent health under the age of 12. Other tests may be necessary in adults to confirm the result of a cutaneous test, but this latter can be advantageously employed as a preliminary in all cases.

4. The Injection or Subcutaneous Test.—This is the last resource and the most searching method of tuberculin diagnosis,[10] and for this reason it is often regarded as the only satisfactory test, in spite of the unpleasant fever reaction. Baldwin[10] regards it as unnecessary in most cases at present, but in instances where a focal reaction is desired, for instance, where a negative cutaneous test requires confirmation, it is of great value. Since the focal reaction in the lung escapes notice in most suspects, the subcutaneous test is of doubtful value in confirming the positive cutaneous reaction.

The most satisfactory tuberculin to employ is Koch's original product, but other filtered extracts may be used. Preparations containing dead bacilli should be avoided; the same is true of emulsions or vaccines, owing to their uncertain and irregular absorption.

Klebs[11] advises the following technique: The site of the injection, which may be under the angle of the scapula or other suitable point, is sterilized, as is also the needle to be used, and the solution of Koch's old tuberculin, diluted with 0.5 to 0.25 per cent. carbolic acid in distilled water, is injected deeply into the tissues. The initial dose differs—Brown advises 0.5 mg., to be followed, if no reaction takes place, successively by 1, 3, 5, and 8 mg. Roepke employs 0.2, 2, and 5 mg. The dose in children must be smaller by 1/10 to ½ than in adults. The reaction appears in 6 to 8 hours as a rule, hence 8 to 10 A.M. is perhaps the best time for the injection.

A positive reaction[9] consists of four phases: (1) The local inflammatory reaction at the point of injection; (2) the rise of temperature; (3) the constitutional disturbance, headache, malaise, prostration, nausea, etc.; (4) the inflammatory reaction in the tuberculous focus. These may appear simultaneously, separately, or two or more in combination, and differ in their diagnostic value; by some the pyrexia and constitutional symptoms are con-

sidered most significant, while others hold that the focal reaction is more pregnant with meaning. If one dose produces a mild indefinite reaction the same amount may be given after two to three days, but the dose should not be increased; Koch regards a strong reaction following a repeated dose as especially characteristic and an almost infallible sign of tuberculosis. The interpretation of results must take into account the amount of tuberculin required to produce the reaction, the promptness with which it develops, and the extent of the local and constitutional sequelæ.

In applying this test care should be taken that the tuberculin solution should be freshly made and accurately measured.

The contraindications are as follows: (1) A febrile temperature; the temperature should not have risen above 99.5° F. in the mouth for at least three days before the test. (2) The test should not be employed when a satisfactory diagnosis can be made without it. (3) Rapid pulse. (4) History of recent hemoptysis. (5) Organic heart disease. (6) Kidney disease. (7) Epilepsy. (8) Addison's disease. The test is inadvisable in hysteria, convalescence from any severe illness, apoplectic habit, marked arteriosclerosis, diabetes, and amyloid degeneration of the viscera.

The subcutaneous test is the diagnostic test of final resort and is the most certain of the tuberculin tests. Like that of the other tests its clinical value is usually in direct proportion to the smallness of the dose and the degree of the response. The more recent the infection and the more extensive the disease the more delicate is the reaction unless the disease is rapidly progressing or grave constitutional weakness is present.[10] In general it may be stated that the tuberculin tests are very valuable when taken in connection with the patient's history, his physical signs, and his constitutional symptoms.

X-Ray Diagnosis.—Klebs[11] considers the fluoroscope of little use as an aid in diagnosis in most instances; at times it will show a contracted shaded apex when dullness and marked changes in breathing cannot be discovered, but this is the exception rather than the rule. Limitation of motion at the base is more commonly to be detected and is more valuable as a diagnostic sign, but too much importance should not be placed upon it. The fluoroscope is of very material aid in the early diagnosis of bronchial gland enlargement, and consequently has a distinct field of usefulness in suspected cases in children.

Rist[12] believes that an increased shadow at an apex may be due to active or old disease or both. When there are symptoms and signs of infection at an apex without an increased shadow on the plate he suspects a fresh involvement in its early stage. A diminished shadow at an apex with no physical signs may indicate active commencing tuberculosis. Radioscopy excels physical examination in its ability to show the extent of pulmonary disease. Beginning central foci are not demonstrable by physical examination, but the *x*-ray may detect them.

Wolff[13] holds that the *x*-ray, in connection with the tuberculin test, enables us to locate the lesion when the latter has proven its existence, the ray being of special value where physical signs are equivocal and the symptoms are suspicious.

Krause[14] finds that in early tuberculosis in adults the fluoroscope will detect apical infiltrations which are recognizable on percussion. The *x*-ray examination is likely to show that the lesion is more extensive than percussion would lead one to suspect. Infiltrations either not demonstrable by percussion or only indefinitely so can often be detected by the fluoroscope, and, when doubtful, confirmed by *x*-ray photographs. Neither the fluoroscope nor the *x*-ray photograph will detect early catarrhal processes, but when these are of long standing the apices may show darkly owing to their poor aeration. These shadows do not clear up on inspiration. Diaphragm pictures may demonstrate the presence of incipient infiltrations which would not be shown by other methods. Calcification of the first rib can be detected, and, according to Freund, is an aid in early diagnosis. The clearing of the apices on inspiration which is present in health is often absent in early tuberculosis. The alterations in movement of the diaphragm are of no diagnostic value.

In incipient infections in children and young people apical findings are lacking, hence detection of shadow changes at the hilum of the lung, such as enlarged, indurated, infiltrated, calcified, or caseous bronchial glands or similar processes in their neighborhood, are the more important. Such findings are of extreme value in early diagnosis, but we must depend on the clinical findings to learn whether these processes are active or no.

The great drawback of the *x*-ray examination in pulmonary affections is the fact that considerable skill is necessary to the proper interpretation of the findings.

Summary.—When it comes to the making of a diagnosis in a case of suspected incipient pulmonary tuberculosis the following factors seem to me to be the most important and the ones on which chiefest dependence is to be placed:

1. The anamnesis. A history of association with other cases of tuberculosis and of previous illnesses such as would point to pulmonary infection is very suggestive.

2. Proper, thorough, and, if necessary, frequently repeated physical examination.

3. Careful observation of the symptoms of toxemia.

4. The cutaneous tuberculin test.

5. *X*-ray examination.

6. As a final recourse, a diagnostic injection of tuberculin.

I have omitted sputum examination from this list because positive results are so infrequent in beginning infections, and because negative results are absolutely inconclusive.

THE METREURYNTER INCISION OF DÜHRSSEN IN THE TREATMENT OF PLACENTA PRÆVIA, WITH REPORT OF A CASE.

By SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

ADJUNCT-PROFESSOR OF DISEASES OF WOMEN, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

DÜHRSSEN was among the first who many years ago appreciated the value of the metreurynter for dilating the cervix in labor and for the induction of labor. In his efforts to bring about rapid delivery, especially in eclampsia, he practised incision of the cervix, by making four long cuts in the cervix, only in those cases where the supravaginal portion of the cervix was completely dilated. In a large number of cases the metreurynter fails, however, of sufficiently rapid action, especially where the supravaginal area of the cervix is not dilated. Since in these cases multiple cervix incisions are contraindicated, Dührssen introduced his so-called vaginal cesarean section, with the aid of which it is possible, at any period of pregnancy or labor, without pains, to so thoroughly remove the opposition of the cervix and lower uterine segment as to make delivery by forceps or version possible at once. There are various methods of performing this cesarean vaginal section. Dührssen uses a longitudinal incision or splitting of the anterior and posterior lips; as soon as the incision penetrates the fornix he pushes up the cul de sac of Douglas posteriorly, separates the bladder from the anterior wall of the cervix and the vagina anteriorly, and then continues the splitting of the cervix up to the peritoneal fold of Douglas behind and the vesicouterine plica in front. My preference has been for the transverse incision in the anterior and posterior fornix with separation of the bladder in front and dissection upwards of the cul de sac of Douglas behind, after which the cervix is split longitudinally to any desired length.

Krönig has practised the method of vaginal cesarean section, but confined himself, in a series of cases, to the splitting of the posterior lip alone. Bumm has confined himself to the splitting of the anterior lip alone. Dührssen is correct in his contention that it is easier to split both the anterior and posterior lips; that the resulting opening is more roomy; that the risk of further tearing of the uterus in the delivery of the head is then reduced to a minimum.

This method is so admirable in its safety and in its rapidity of execution that its use in placenta prævia was a great desideratum. To carry out this step in placenta previa, one is confronted, however, with cases where the bleeding commences and is so profuse as to render the field of operation unapproachable for operative interference. In other cases, the incision would enter the sphere of the placenta and start a hemorrhage that would totally obscure the operative field.

Dührssen has overcome these obstacles by combining the vaginal cesarean section with the use of the metreurynter. In other words, the metreurynter is introduced; it is filled with lysol or some other antiseptic solution and then the anterior wall of the cervix alone, or both the anterior and posterior walls are split, producing an opening through which version and extraction are rapidly accomplished. The metreurynter during this procedure dilates the lower segment of the uterus, thoroughly controls bleeding from the placental site, and renders the parts of the uterus to be incised so anemic that only a very small amount of blood is lost, and that almost entirely from the posterior incision.

Mrs. B., pregnant for the second time, at the stage of 7½ months, commenced to bleed suddenly and profusely. Vaginal examination disclosed a vertex presentation, a cervical canal that admitted one finger, and a placenta prævia marginalis. The vagina was thoroughly packed with iodoform gauze and patient removed to the hospital. Under anesthesia, after thorough preparation of the vulva and emptying of the bladder, the vaginal iodoform gauze packing was removed and a posterior vaginal speculum was introduced. The anterior lip of the cervix was grasped by bullet forceps and the metreurynter was introduced, was filled with lysol solution, and the tube was clamped. The posterior retractor was removed, an anterior retractor introduced, and traction on the tube of the metreurynter brought the cervix down to the vulva. A wide transverse and somewhat curved incision was made through the anterior lip of the cervix ½ inch above the external os. The upper margin of the incision was grasped by two long artery forceps and the bladder was thoroughly dissected away from the anterior wall of the cervix up to the vesicouterine plica and the anterior speculum was now introduced between the bladder and the cervix. A long pair of straight blunt-pointed scissors incised the anterior wall of the cervix over the metreurynter for a distance of 2½ inches. The metreurynter was pulled on more forcibly, the anterior speculum was pushed higher up, peeling the peritoneal fold away from the anterior wall of the uterus. The anterior incision was increased in length up to the peritoneum. The anterior retractor was removed and introduced posteriorly over the perineum, the metreurynter was pulled up toward the urethra and the posterior wall of the cervix was incised for a distance of 1½ inches. The finger was introduced between the vaginal mucosa and the cervical tissue, and the cul de sac of Douglas was pushed upward. The posterior wall of the cervix was split up to the peritoneum and the resulting opening was so large that the metreurynter made its exit. The hand was then introduced, the membranes were ruptured, version was executed, the leg was pulled down and within the space of a few minutes extraction was completed. The placenta and membranes were removed manually, and a very hot vaginal lysol douche was given. Before the metreurynter had been introduced a hypodermic injection of ergotol was administered and another was now given. Bleeding had almost ceased, and a very wide strip of iodoform gauze had been introduced into the uterus extending out beyond the vulva. The two halves of the split cervix were grasped by volsella and others were put on at higher points until the upper area of the incision was reached. The bladder was held up and out of the way by an anterior speculum and the incised cervix was closed by interrupted chromic catgut sutures applied ½ inch apart, nine sutures in all being passed. Care was exercised not to catch the iodoform gauze which lay in the cervical canal. The cervix was then pulled up toward the urethra and in the same fashion the incision in the posterior lip was closed. Two chromic sutures were passed through the transverse incision along the anterior fornix and a narrow strip of iodoform gauze was introduced between the

bladder and the anterior wall of the cervix. The intrauterine gauze was taken out, another intrauterine douche was given, and a narrow strip of gauze was passed through the cervical canal into the uterine cavity. The vagina was packed with iodoform gauze and the operation was completed. The strip of gauze between the bladder and the cervix was drawn out at the expiration of 48 hours; the intrauterine strip at the end of 4 days and the vaginal gauze at the end of 5 days. Convalescence was uninterrupted and rapid.

In treating placenta previa, we may either introduce a metreurynter, allowing it to remain until dilatation of the cervix is complete, or we may rupture the membranes, so that the head may be forced down and compress the placental area, or we may do a version, draw the leg through and permit labor to follow a natural course. If the cervix does not permit the ready introduction of the hand for the performance of version and extraction, none of the above methods compare as regards safety and rapidity with this method of Dührssen.

NEURITIS.*

By WILLIAM BENHAM SNOW, M.D.,

NEW YORK.

Pain has often been described as the indication of impaired nutrition—the "cry of hungry nerves for better blood." That this view is the rule is a debatable question. The word neuralgia is the outcome of this idea and the habit of calling pain, wherever located, neuralgia, or attributing it to so-called "rheumatism" is unfortunate and unscientific. The term neuralgia, as applied to sciatica, and facial neuritis, with the pathology of the conditions in doubt, is not distinctive. In observations taken from more than two hundred cases of pain involving the distribution of the sciatic nerve and its branches, and about an equal number of cases of brachial neuritis, the writer has failed in but very few cases, and those remote, to localize a circumscribed local lesion. The same has been true in all cases of pain involving the branches of the trigeminus.

The diagnosis of neuritis, with the localization of the site of the lesion, is of the utmost importance, if the case is to be treated successfully. These observations have caused us to make the preceding statements concerning neuralgia; for in few cases except possibly the pains of tabes, where the process may readily be referred to an irritating or inflammatory process involving the central neurons, is it difficult to locate a local inflammatory cause of pain.

The pathology of neuritis, as the word implies, is always referable to an inflammatory process involving the neurilemma, or the nerve trunk or both, and in some cases accompanied by an interstitial process involving all the structures of the nerve trunk in the affected segment. The inflammatory process very rarely if ever destroys permanently the axions of the nerve trunk, except when involved in a malignant or some other destructive process. An acute unarrested neuritis may result in the formation of adhesions between the nerve sheath and the surrounding structures, and thereby create considerable hyperplasia which may for a long time impair the functions of the nerve, and be accompanied by a persistent more or less painful condition. The inflammatory process in neuritis is as a rule circumscribed within a small area, while the pains or a sense of numbness are referred as a rule to the periphery, corresponding with the axions upon which the pressure is exerted. The fact that these localized areas have not often enough been recognized has probably led to the abuse of the term neuralgia. There are certain exposed regions which are common sites of the lesion. Such lesions are usually located at points where the nerve trunk crosses a bony prominence or fibrous structure particularly when a muscle is over a nerve in an exposed part of the body, as in the following frequent sites of neuritis; where the sciatic nerve at the sacrosciatic notch passes beneath the pyraformis muscle; where the crural nerve passes beneath Poupart's ligament; where the lumbosacral cord and the anterior crural cross the sacroiliac synchondrosis; where the musculospiral and circumflex emerge from beneath the teres minor; where the suprascapular passes out beneath the trapezius and enters the supraspinatus fossa of the scapula; where the inferior dental enters the canal in the inferior maxillary bone; where the superior maxillary or second division of the fifth cranial nerve emerges through the infraorbital foramen. These exposed points explain the traumatic origin of a large percentage of the cases of neuritis, the peculiar conditions accounting for frequent occurrence at these sites. In herpes zoster and intercostal neuritis deep pressure made in the intervertebral spaces over the posterior roots will elicit points of tenderness.

Etiology:—In addition to mechanical injury or exposure, toxemia or local infection is a factor in the etiology of some cases of neuritis, as is indicated from the fact that some cases have favorably responded to so-called "anti-rheumatic" remedies.

Treatment: Whether a localized neuritis is of traumatic or of infectious origin, when it has persisted for two weeks or more, it will not respond favorably to drug treatment; as is borne out by experience. While exceptional cases may recover spontaneously, the usual case of neuritis under the medical régime is the *bête noir* of the medical man. The variety of means, medicinal and mechanical, that have been employed in the treatment of neuritis in the past is indicated by the large number of remedies prescribed. Rest, fixation splints, nerve stretching, surgical operations, and the employment of so-called antirheumatic remedies, followed in many instances by hot baths at the various health resorts and spas, are the usual régime employed in the treatment of neuritis; at least so we are to infer from the text book and the frequent reports of unrelieved sufferers that have come to be relieved. That these methods have been followed with only a moderate degree of success is evidenced by the large number of chronic cases of neuritis.

That there are methods of treatment which meet with uniform success when the lesions are accessible, *i. e.*, not in the pelvis or cranium, is the author's object in presenting this paper. It has been my lot during the last twelve years to have had under observation a large number of these cases in which the results have been uniformly satisfactory. The principles of treatment employed have been as follows: Accepting the fact that a local inflammatory process is always associated in its early stages with the development of induration—the stasis of inflammation—it is self-evident that induration thus formed exists as an obstruction

*Read before the Third International Congress of Physiotherapy at Paris, France, April 1, 1910.

to the blood stream, with the infiltrating materials, fibrin and round cells in process of being thrown out into the lymph spaces and there becoming gradually organized and often causing the nerve to become adherent to surrounding structures. These in turn exert pressure upon the nerve trunk and end nerve plates, producing local or diffused pain or both, together with impaired nutrition, varying with the length or extent of the nerve trunk involved; the pain as a rule being most marked at the periphery.

The indication for the treatment of inflammation, with the associated processes of infiltration, producing pressure and pain, is the dissipation of such infiltrating materials. With tissues thus involved in any noninfected inflammatory process, the infiltration with swelling and tension may be dissipated in the early stages, before organized hyperplasia has taken place, by inducing intrinsic activity, in other words, successive structural contractions throughout the area involved, and of the surrounding muscles, thereby forcing out or expressing the foreign substances from the lymph spaces. To be more specific, if an electrical current is applied to a structure in a state of infiltration, inducing successive contraction with intervening intervals of rest at an alternating rate of about 120 per minute, it will express the fluid element of the exudation, and also induce the elimination of round cells and fibrin deposited in the lymph spaces. This is practically demonstrated by the application of the static wave current or static sparks to a recent sprain which is thereby softened by one application to the extent that the patient who enters the office with difficulty walks out with little pain after the first administration. This principle in therapeutics applies to the treatment of all conditions of noninfected inflammation including the types of neuritis.

Another element to be considered as present with neuritis, and also in joint inflammation, is the associated condition of tension or contraction of the muscular structures receiving their nerve supply from the affected nerve, or the muscles which cross or move a joint. In neuritis of the brachial plexus, such contraction may cause the fixation of the pectoral, triceps, teres minor and major, biceps, and deltoid muscles; in severe cases to an extent that will so immobilize the arm that movement is both painful and difficult. It is this condition of muscular tension and contraction which gives the arm or limb the seat or a brachial or sciatic neuritis the sense of weight or heaviness and disuse. These conditions of muscular contraction are practically relieved by the same means as relieve local induration and infiltration.

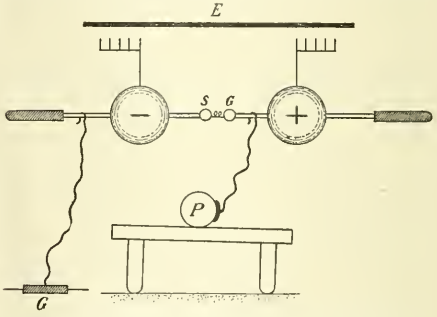
Effectually to overcome the infiltration and muscular tension associated with the local lesion of neuritis, there are no means, in my experience, that compare with the static modalities, particularly the static wave current, the static sparks, and the static brush discharge, as well as in some cases the direct vacuum tube current which simulates the wave current in that it is administered with the vacuum tube connected in the same manner to the positive pole of the static machine, with the negative side grounded, and the spark discharging at a length that can be tolerated by the patient. (See the illustration.)

Radiant light and heat or dry convective heat, as an adjunct to static treatment, should never be employed following the administration of that current. If, however, it is applied prior to the static treatment, the capillary and arterial dilatation induced, together with the tissue relaxation, seems to facilitate the expression of the debris or infiltration from the tissues, whereas relaxation so induced following the static treatment tends again to flood the tissues and produce to a degree a secondary infiltration. This has been well demonstrated by relapses thus induced in connection with the static treatment.

The application of mechanical vibration in the treatment of neuritis, associated with the static administration aids in overcoming the muscular tension. Otherwise, in our experience, the employment of this agent has proved generally unsatisfactory.

The technique we employ in the treatment of the variously located cases of neuritis is substantially as follows: If there is great pain and diffuse tenderness of the parts, as in acute cases, the application of radiant light and heat from a source of high candle power, to the extent of inducing an intense local hyperemia over the sensitive part, should always precede the application of the static wave current, which is administered in the following manner:

The patient is seated upon the insulated platform, opposite the positive pole of the machine, a metal electrode of lead, block tin, or bottle cap composi-



Connections for Static Wave Current. E, Electrostatic Generator; G, Ground Connection of the negative side of the machine; Electrode is connected to patient, P, who must be insulated.

tion (22 gauge is the best thickness) adapted to the part to be treated is adjusted over the site of the lesion, and fixed in such a manner that it will be held in close apposition to the skin, either by pressing it against a pillow, placed at the back of the part to be treated, or by bandaging the electrode to the part.

In the treatment of tic-douloureux, the pliable metal should be shaped to fit the face in such a manner that it will cover and press upon the distribution of the affected nerve. The electrode is best held in place by the palm of the bare hand of the patient against the metal, the arm resting upon the arm of a chair. It is impossible to administer this current over the forehead or scalp, on account of the thinness of the aponeurosis and skin, and the intense painful vibration induced over the bony structures beneath; but here the static brush discharge is always effective. The electrode, having been placed in position, is connected by a rheophore, a small bare wire suiting the purpose, to the positive side of the machine. The spark-gap or space between the discharging rods is then closed, and the negative side of the

machine grounded to some direct grounding, as a water pipe or radiator. The machine is then started at a very slow rate of speed, and the operator proceeds to open the spark-gap slowly, until the patient complains of too great pain, produced by the contractions induced in the involved tissues. A spark-gap one inch or a little more employed when treating an involved sciatic nerve at the notch, employing a metal electrode four or five inches square is all that can at first be tolerated if a lesion is present. Severe pain induced in this manner will be diagnostic. The spark-gap should then be opened a little at a time by the operator as the patient can tolerate it, until the treatment has been continued for twenty minutes, when the spark-gap may have been lengthened to from three to four inches. By this time the contraction or tension of the pyriformis and gluteal muscles will have been relaxed, and the infiltration be largely expelled from the involved tissues. The extent of relief that this treatment will afford the patient must be experienced or the effect witnessed to be appreciated by those who are unfamiliar with this method of treatment. The patient who comes in a cab and enters the office with difficulty, often can walk home without assistance.

It is my custom to follow up this treatment with a few static sparks over the section of nerve involved, and to any muscles that are tense and contracted, as to the long muscles of the internal and external vasti and quadriceps groups which are apt to be contracted in sciatica and the deltoid, teres minor and major, pectoral, triceps, biceps, and scapular muscles in brachial neuritis. The application of a spark to a muscle thus contracted will cause marked pain, but a very few sparks carefully applied completely relax the tense muscles. It is customary to apply these sparks to the long muscles in rapid succession with the sparking ball passing parallel to the involved muscles. Sparks cause intense pain, temporarily to be sure, when applied over the site of the lesion in neuritis, but no modality will be missed more, if this application is neglected.

Patients will accept it without protest as soon as they discover the relief following the application, and if not completely relieved will ask for more. It is notable how these patients will call for here and there another spark. It is customary in treating neuritis when seeking to overcome muscular tension, following the treatment of the local lesion, to have the patients move the affected arm about in all positions which cause pain, indicating where pain is caused by the movement, and there to apply sparks.

Few patients who have suffered for a few days or one week with a severe neuritis will make protestation against the application of these measures, if they are intelligently applied; the relief is so instant and complete. The length of sparks administered should always be relative to the size of the part involved—sparks an inch long over the forearm, to two and one-half inches over the deltoid and four inches over the glutei muscles and muscles of the leg, will be an approximate length in an average case to insure a maximum benefit. Sparks are best localized in these cases by means of a spark director.

In the treatment of tic douloureux or neuritis of the trigeminus, variously located, the application of the wave current will be followed to advantage in most cases by the use of the static brush discharge instead of sparks; the structures being less dense, this modality will always be effective. When the lesion is in the mouth, a glass vacuum tube electrode held over the lesion and employing the direct vacuum tube current obtains the desired result. It was so employed to two of my patients; one a case of neuritis of the inferior dental branch, where the nerve entered the bony canal, and in the other case the electrode was applied above the upper alveolar border.

In herpes zoster the static brush discharge is the modality of election for application over the herpatic patches, following an administration of radiant light and heat. Over the unerupted area, apply an electrode of soft metal which will cover the parts that are contracted and painful, and employ the wave current daily or twice daily in severe cases for twenty minutes, followed each time by sparks directed to the intervertebral spaces along the spine until the pain is relieved. These measures effectually cure these cases in a few days, and promptly relieve most if not all of the discomfort at each application.

Intrapelvic neuritis frequently occurs, associated with the sacroiliac luxation described by Goldthwaite. These cases are promptly relieved when coming early under observation, by the systematic employment of the static wave current with an electrode of soft metal $3\frac{1}{2} \times 8$ inches in dimension, applied over the sacroiliac synchondrosis and contracted muscles of the gluteal region, and employing at first a spark-gap as long as the patient will permit it, gradually increasing it to from six to ten inches, for the usual twenty minutes, followed by static sparks and in severe cases by an additional internal treatment such as is used in treating prostatitis with a cylindrical metal electrode, carried high up into the rectum, and held against the affected side. The writer has successfully treated four of these cases during the last two months, in all of which recovery has been complete within two weeks. In some cases it will also be necessary to reduce a luxation at the synchondrosis by extreme and forcible flexion of the thigh upon the trunk. It is probably these cases that are thus relieved by so-called nerve stretching.

The prognosis in neuritis when the static modalities are employed is always good by the method described, if the lesion is accessible. The time necessary to effect a cure is relative to the chronicity, *i.e.*, relative to the amount and character of the exudation and the extent of the involvement or lesion, when the case comes under observation. In no instance has the writer failed to cure a case of sciatic neuritis of less than two weeks' duration within ten days, the cases of shorter duration being relieved promptly with from two to five treatments.

In chronic tic douloureux the prognosis is bad after two years, because the lesion located within the bony structures is inaccessible, and the induration has become organized. These cases, however, are promptly cured when of less than one year's duration; and cases of Bell's palsy not of cortical origin respond to the same treatment for the same reasons.

There is probably no technique in electrotherapeutics that requires more care and precision in the management than the treatment of neuritis, and none that affords greater satisfaction to physician and patient.

STRICTURE OF THE MALE URETHRA.*

By WALTER BROOKS BROUNER, A.B., M.D.,

NEW YORK CITY.

STRICTURE of the urethra in 95 per cent. of all cases is due to the after effects of one or more attacks of gonorrhea; congenital, traumatic, inflammatory, spasmodic, and organic strictures constituting the remaining 5 per cent. The importance of a knowledge of the cause and effect of strictured urethra cannot be overestimated, as gonorrhea is so prevalent in the male population of all cities, towns, villages, and hamlets as to be practically endemic. Indeed, so common is it, and of so little importance to the average citizen who is afflicted with gonorrhea, that it is often looked upon as a joke and of no more importance or danger than an ordinary cold in the head.

The attitude of the public, due to ignorance of the seriousness and latent possibilities of "only a dose of clap," makes the proper care and after treatment of a case of gonorrhea one of the most trying problems with which a physician or genito-urinary specialist is confronted. My hospital and private records show that not more than 50 per cent. of those afflicted with gonorrhea are willing to follow out the after treatment of their gonorrhea until cured; whereas 95 per cent. of our syphilitic patients haunt our offices until they are told to quit treatment. And yet this disrespect for gonorrhea, in spite of the fact that it causes not only stricture of the urethra, abscesses about the genital organs, disease of the testicles causing sterility, involvement of a very important organ—the prostate gland, infection of the bladder, urinary ducts, and kidneys, but also inflammations of the various tissues of the body, such as joints, bursæ, tendons, muscles, the heart, and even the eyes.

Of all these complications stricture of the urethra, excepting perhaps prostatic involvement, is by far the most common, often leading to the most serious complications to the genitourinary economy, and often necessitating heroic measures for relief of the patient. Why, then, is stricture so prevalent as a result of gonorrhea? The reasons are simple. The natural configuration of the urethra or urinary pipe predisposes to it; also the causative agent of the gonorrhea, the gonococcus of Neisser, with its predilection for the deep tissues, produces an ulceration of the mucous membrane of the urethra with a proliferation or deposit of new tissue within the urinary canal, and finally, patients refuse or fail to persist in their treatment of gonorrhea until cured.

The normal urethra is, as we know, not of equal or uniform caliber throughout its entire length. "At the meatus urinarius or mouth of the penis we find a normal narrowing of the canal, which then expands into a spindle-shaped portion, which is called the fossa navicularis; hence this is called the navicular portion of the urethra. As this part emerges into the spongy or penile portion a slight constriction occurs. The canal then expands and we find it of somewhat uniform caliber in its course through the course of the corpus spongiosum for a distance of four or five inches. It then expands again, in conformity with the bulbous expansion of the corpus spongiosum, and a spindle-shaped canal is formed, which is from an inch to an inch and a half in length, and is called the sinus of the bulb or bulbous portion of the urethra. Again becoming contracted at the anterior layer of the triangular ligament it has a uniform caliber for a distance of about three-quarters of an inch, when, at the posterior layer of this ligament, it emerges to expand again into the prostatic urethra. In its course through the triangular ligament it is simply a membranous canal seated about an inch beneath the summit of the pubic arch, and surrounded by the compressor urethræ muscle. The prostatic urethra is the direct continuation of the membranous urethra. It also has a spindle shape and is about an inch and a quarter in length. Thus anatomically there is a navicular, a spongy, a bulbous, a membranous, and a prostatic portion of the urethra, making five divisions in all. The term 'penile' or pendulous urethra is also applied to that portion which extends from the glans to the penoscrotal angle."

This configuration of the interior of the penis, together with the numerous ducts or pockets in the membrane of the urethra, form a natural nidus for the gonococcus, which if not eradicated tends first to a mucous degeneration of the mucous membrane, the formation of transitional cells, and finally a subepithelial connective tissue formation, which if not checked, leads to a round cell infiltration of greater or less extent.

According to Finger, "the areas of gonorrheal urethritis localize themselves by preference in the pendulous, bulbous, or prostatic portions of the canal, the membranous portion being rather immune to chronic inflammation of this sort." If the gonococci are not eliminated and the chronic urethritis terminated, the granulation tissue persists. Contraction subsequently occurs, causing stricture, which we define as any narrowing in the lumen of the canal or pipe or urethra. A stricture may be either (a) linear, (b) annular, (c) tortuous, depending on the relation of the scar tissue to the canal or urethra—in short, strictures vary in degree rather than in kind, and also as to the extent that they tend to a closure or occluding of the canal; hence the arbitrary distinction of open or large caliber strictures, and tight or small caliber strictures.

The changes which now take place, due to the existence of the stricture, are produced, first, by mechanical influence and, second, by infection. The urine in its outward flow meets the obstruction presented by the stricture, causing increased pressure on the walls of the urethra. This back pressure is felt all along the urinary canal, extending eventually to the bladder, which now has to work harder and overtime in order to expel its normal urinary contents. This constant overwork on the part of the bladder causes either hypertrophy of its muscular walls or it loses its contractile power, and atony or loss of bladder tone results. If the stricture be not relieved this damming-up process may back up into the ureters, which connect the bladder with the kidneys, subjecting them to similar deleterious pressure influences as described in the bladder, until the kidneys are involved, undergoing either a compensatory hypertrophy or a dilatation of their pelves. Finally the very substance of the kidney is involved, and water-logged or hydronephrotic kidneys result.

Concomitant with these muscular processes there go hand in hand other changes. As the bladder loses its projectile or expulsive force a certain

*Read before the Genito-Urinary Section of the New York Academy of Medicine, May 18, 1910, in a symposium on "The Complications and Sequelæ of Gonorrhea.

amount of urine is left behind, either behind the stricture or in the bladder itself. This urine undergoes fermentative changes, which not only tend to perpetuate the local inflammatory conditions but aggravate them, hence the ducts and the glands of the urethra become inflamed. Periurethral abscesses form. If the stricture be excessively tight a complete shutting off of the stream of urine results, causing retention of urine, which if not relieved causes urinary extravasation or leakage into the adjacent tissues. This in some cases leads to death, or if the case does not progress so far as this, cystitis may occur and with it a transmission upward and backward through the urinary apparatus, until the entire genitourinary system is involved with a pus infection.

It is impossible to state what proportion of patients who have had gonorrhea become the victims of strictural formation. It is certain that if a gonorrhea be gently, systematically, and persistently treated until the urine is free from shreds and gonococci and the subsequent course of after treatment by sounds be instituted, we can then predict the absence of any subsequent stricture formation. Once formed, strictures may vary in number, as many as ten strictures having been observed by me in one case. Observers vary as to the site of strictures. In one hundred cases observed by me at the New York Hospital and Vanderbilt Clinic thirty-five were within the first two inches behind the meatus urinarius, forty-seven were between the latter point and the penoscrotal junction, eighteen were at or near the penoscrotal junction. Strictures of the prostatic urethra are rare and with difficulty demonstrable.

The symptoms in the order of frequency are (a) gleet, (b) change in the stream either as regards form, force, or size, (c) increased frequency of micturition, (d) bladder symptoms as already described, and (e) loss of sexual power. The limits of this brief paper will not permit of any extended reference to these symptoms.

The diagnosis of stricture is made from the symptoms which the patient presents as already described, and from our examination of the urethra. Suffice it to say that we employ in our investigations two sorts of instruments: (a) metallic instruments, *e.g.*—cone-pointed or olive-pointed bougies, tunneled and grooved silver catheters, and tunneled and grooved metallic sounds, metallic urethral sounds, the urethrometer, dilators, and the endoscope; (b) non-metallic instruments: *e.g.*—filiform whalebone guides, soft flexible silk or lisle thread bougies, and rubber silk, or lisle thread catheters, without going into detail, it is necessary to remember that all our instrumentation must be of the gentlest nature. Force must be omitted, and patience and persistence substituted.

The treatment is prophylactic, nonoperative, and operative. (a) By prophylactic I mean that gonorrhea should be conscientiously treated so that the possibility of stricture following an attack of gonorrhea may be eliminated. In my practice I begin the passage of soft instruments as soon as the gonococci have disappeared. Many obstinate cases with shreds in the urine directly following an attack of gonorrhea clear up under sound introduction, after local applications, such as silver nitrate, have failed. No patient should be discharged by us as cured until a thorough exploration of his urethra has been made.

(b) Nonoperative treatment. As we have already indicated, strictures are open or closed. In my experience a large majority of strictures are amenable to dilatation. Even though at first admitting but a filiform, we may gradually, with tunneled instruments (followed by soft instruments later), work them up to at least 20 Fr. and then continue our work with rigid instruments, until we have dilated the urethra up to what we consider the normal size for the given individual. The results of such treatment so far as permanency is concerned are just as good as those following cutting operations, if not better, for even when operative treatment is employed we are forced to use dilators (sounds) thereafter for a certain interval. In all our manipulations of the urethra we must not employ force, but gentleness coupled with patience and persistence. The mortality of such dilatations is practically nil. Divulsions are not desirable, as they do too much violence to the urethral structures and eventually leave the patient as badly off (if not worse) than before the treatment.

(c) Operative treatment. There are certain cases which are not amenable to dilatation. Then there are certain emergency operations, such as retention, fistulæ, extravasation, etc., which require operation on the urethra. We then have one of three operations to perform—viz., internal, external, or combined internal and external operations. The limits of this paper will not permit of any reference to the detail of such procedure. It will be sufficient to state that like all cutting operations, there is a certain degree of danger from hemorrhage, infection, anuria, etc. Operations on the urethra today are not so numerous as formerly, and are accompanied by a relatively decreasing mortality, owing to our advanced ideas as regards preliminary and after treatment, and our special improved surgical equipment and technique.

27 West Ninth Street.

A New Technique in Intrabronchial Injections.—Guisez describes a new method by which intrabronchial injections may be easily carried out. He gives the results of such injections in a case of acute intrapulmonary abscess and one of chronic bronchial dilatation. In the abscess case radioscopy enabled the abscess to be located, and the treatment brought about a speedy recovery. In the chronic dilatation case the patient was benefited by the injections, and his fever lessened by the emptying and disinfection of the bronchiectatic cavity. The larynx of the patient is cocainized and the injection made with a long curved cannula, which is introduced with the head mirror. The cannula reaches to the bifurcation of the bronchi and is directed toward the affected bronchus at the moment of injection. When the injection is made the patient lies on the affected side, so that the solution runs in that direction. It is possible to introduce without disagreeable results 12 to 18 c.c. of fluid. This method allows of efficient local treatment of pulmonary conditions.—*Gazette des Hôpitaux.*

The Blood in Kala-Azar.—A. Tomaselli has investigated the blood in kala-azar to find if there is any diagnostic criterion in it by which to differentiate the varieties of this disease from one another and from other similar diseases. He does not find such practical differential criteria. In the beginning of the disease there is a moderate leucocytosis; later there is anemia; increased globular value; lessened hemoglobin and erythrocytes; increased mononucleated leucocytes; lessened lymphocytes; eosinophiles; and no alteration of size and form of red cells. Chromatophilia is noted in some cases. There is some difference between the blood in the African and Egyptian varieties. The parasites are rare in the peripheral blood. In infantile pseudoleukemic anemia there are numerous hematoblasts; there are nucleated red cells, which are rare in kala-azar. In malarial anemia we find malarial parasites in the blood, polynucleosis, and eosinophiles. In Malta fever there are normal polynucleated neutrophiles, polynucleates, and eosinophiles.—*Rivista Critica di Clinica Medica.*

ARTERIAL HYPERTENSION.

SINCE the introduction of the sphygmomanometer into clinical medicine has done for the estimation of blood pressure what the clinical thermometer years before did for the body temperature, great and widespread interest has been taken in the interpretation of the variations and fluctuations of this particular factor of the pulse. This sudden enthusiasm has done much good in teaching the physician the necessity of careful observation of the pulse force, both as an aid to diagnosis and as an indication for treatment. Along with its benefits, however, the sphygomomanometer has done a certain amount of harm, for with its steadily widening use the term "arterial hypertension" is beginning to be used almost as though this were in itself a disease instead of merely a symptom.

For a proper understanding of the treatment of the various conditions associated with which the arterial pressure is above normal, it must primarily be recognized that if the pressure is high there must be some underlying cause for the abnormality. Such causes can, as a rule, be divided into three groups: mechanical, nervous, and toxic causes. The most common mechanical cause is arteriosclerosis, and yet there may be pipe-stem arteries with normal pressure. The reflex nerve irritation of a peritonitis or a fright, may cause a sharp rise in pulse tension, but in shock the blood pressure falls. The cause of hypertension, which is probably the most widespread and the most frequent, is intoxication. It is generally considered that it is the irritation from poisons retained by the kidneys and not the mechanical obstruction which sends up the blood pressure in nephritis, while in two articles in the *American Journal of the Medical Sciences* for May and July, 1910, Elliott emphasizes the toxic cause of those indefinite cases in which the pressure is permanently above normal, without recognizable causative lesions, the cases called by Cook "essential arterial hypertension."

These cases occur, as a rule, in stout people of middle age, often in men of large affairs leading strenuously active lives, and considering themselves to be in good physical condition. A little headache, some "biliousness," constipation, vertigo, or, most frequently of all, a troublesome flatulency appearing at night or excited by exertion brings such patient to the doctor with the self-made diagnosis of indigestion. An examination reveals a slightly plethoric man, with possibly more or less cardiac hypertrophy, and a systolic blood pressure between 160 and 220 mm. of mercury. The liver may be enlarged and an excess of indican is found in the urine, but, at least in the earlier stages of the disease, there is no sign of renal involvement. In such cases Elliott believes that the hypertension is due to the stimulation of poisons circulating in the system, toxins having their origin in the intestines, which keep the muscles of the vessel walls in a constant state of spasm, causing increased resistance to the flow of blood, and ultimately arteriosclerosis and cardiac hypertrophy.

The treatment in such cases is chiefly hygienic and dietary, and may well be summed up as moderation in all things. The patient must not starve himself, and he must not overeat. A low meat diet is desirable, but an embargo on meat with license in carbohydrates is distinctly harmful. Violent exercise must not be indulged in, but a sedentary life aggravates the condition. The use of alcohol and tobacco should be kept within moderate limits, and the salt intake should be reduced. Water should be given freely and the bowels should be kept well open with saline cathartics. When the pressure lies within moderate bounds and no active symptoms are evident, vasodilators are unnecessary. When the pressure is extreme and symptoms giving warning of an approaching apoplexy appear, active vasodilatation with nitrites is urgently required. In the later stages, when the heart has hypertrophied and then weakened, stimulants are needed, a reliable indication for this being the response of the pulse and blood pressure to graded exercises. If during exercise the pressure rises gradually and remains high for some time, the heart is in good condition; if it drops quickly to a point lower than before the exercise began the heart is weak.

These communications of Elliott are of considerable value, not only as pointing out what the author has found to be the most satisfactory method of treating a very puzzling and resistant class of patients, but especially in emphasizing the need of recognizing the underlying causes of the condition.

A FISH DIET.

SIR J. CRICHTON-BROWNE, who is the orator of the British medical profession, has been lauding recently in eloquent language the merits of a fish diet from various standpoints. At the twenty-fifth annual conference of the British Sanitary Inspectors' Association held in Fishmonger's Hall, London, on August 30, the speaker in question discussed fish generally. In the first instance he proffered the very sound advice that systematic inspection should be maintained over all sources from which shell fish were sent to market and that samples of the fish so sent should be taken frequently and subjected to bacterial examination in the same way as milk was tested in order to prevent the spread of disease. The main part of the address was devoted to the discussion of fish as a food, and regret was expressed that away from coastal towns fish had hitherto been regarded too much as an accessory,

too little as a staple article of diet. There are large numbers of people in rural districts, and the remark applies more pertinently to America than to Great Britain, who rarely taste fish, and who indeed fail to realize the value of fish as food. Fish, from a physiological point of view, except, perhaps, from the point of view of the vegetarian, is the next best thing to meat. It contains less protein than meat, and as a source of energy its nutritive value varies with the amount of fat it contains. In this respect salmon may be considered as equal to lean meat, but the lean fish which contains less fat and more water has to take a lower place. It has been calculated that 1½ pounds of codfish will equal in nutritive value one pound of lean beef, but cod is far cheaper than beef. Still the market price of fish is no criterion of its nutritive value. Sole is dear, while haddock is cheap, but haddock contains as much nutriment as sole. As a matter of fact, scarcity, taste, and fashion, and perhaps prejudice, regulate the market for fish, as there are several species of fish which are edible and nutritious, but which find no favor with the public.

Browne points out that if a general call for fish were to arise, a vast development of the fishing industry would take place, and we might look forward to an abundance of good nourishing and digestible fish for the people at a price making it accessible to the poorest. But in order that fish as a food should become widely popular, it is necessary that its merits should be made known far and wide, and especially among the poorer classes.

In the address given in London a very interesting point was brought forward, that the campaign against tuberculosis might be greatly aided by an abundant supply of cheap fish. Power of resistance to the disease is an important factor in its prevention, and that power is lowered by poverty in its many phases, and conspicuously by poverty in food, and especially by nitrogen starvation, as it is called, or an insufficiency of protein in the nutriment supplied. Little emphasis is needed to prove that if the sick poor were better fed their powers of resistance to tuberculosis would be greatly strengthened. Therefore the argument that to render fish foods rich in protein accessible to the very poor would be to take a long step toward the abolition of tuberculosis, seems quite reasonable.

There is one point in support of fish as food upon which the speaker did not touch, that it is not only a cheap alternative to meat, but that it possesses some special properties of its own. It is usually very digestible, and in these days when indigestion, intestinal fermentation, and the like are the most common disorders this is a very great feature in its favor and should particularly commend it to an American public. It should also be borne in mind that there are as good fish in the sea as ever came out of it, and that the succulent and nutritious varieties are not only those that are known and appreciated, but some which are unknown, and other varieties against which a prejudice exists.

It is certain that fish on the whole is nutritious, that many nutritious varieties are cheap, and the advice of Sir James Crichton-Browne might be followed with advantage in the country. For reasons hard to understand fish is neither so plentiful nor so cheap in New York as its situation seems to demand. Neither as an article of diet is it very largely used among the poor. A campaign of education on the beneficial effects of fish as a food would be as productive of good results in New York as in London, and the day may come when fish will be a common article of diet in the homes of the poor in Europe and in America.

The Mental Exertion of Manual Labor.

The belief is perhaps general that manual labor involves no particular mental strain. On the other hand, one frequently hears it said that mental work prejudicially affects the bodily powers to a much greater extent than does manual labor. Although there is a considerable amount of truth in the statement it must be accepted with certain distinct modifications, for even those who literally earn their daily bread by the sweat of their brow are not wholly exempt from brain travail. A correspondent of the London *Times*, August 29, argues the case ably for the man with the hoe or axe. He points out that it is impossible to draw a precise line between mental and manual work. Physiologically all work is brain work. All fatigue is really brain fatigue. In other words, all labor is skilled labor, though in greatly varying degrees. The navvy with his pick and shovel has to use skill; so does the docker, loading or unloading barrels, cases, and bales. There are men who are so constantly engaged in carrying out one little process that they do the work instinctively, almost automatically. The exercise of their skill requires little exertion of body or mind. On the other hand, the watchmaker or the engineer has to keep his mind continually on his work, and although he must use his hands all the time, his brain is being exerted more than his body. Many indoor trades requiring skill need the employment of brains rather than of physical force. But even the horny-handed son of toil, as the Italian who digs, and delves, and blasts, and the countryman who toils on the land, in these days of machinery must use a good deal of intelligent, as well as expend much bodily, energy. Indeed, it is obvious that brains are required in all trades and possibly on the whole nearly as much mental power is used by the man who works with his hands as he who mainly uses his brains. The professional man or the business man is generally brought up and educated for his work and thus his brains are trained, while the uneducated individual has, so to speak, to work his brains more, in that they are untrained. Whether it be work of brain or hand, so long as it is not carried to excess, it is healthy. No healthy man has ever been killed by hard work within reasonable limits, of any kind. More have rusted to death than have been worn out. The work which kills at the present time is the abuse of work, the rush and strain of modern conditions, and, above all, worry, the curse of modern times. The person who works at hard manual labor has several advantages. As a rule, he labors in the open air, and provided that he earns sufficient to support himself and family in comfort he is free from worry and he is free from responsibility which usually brings worry in its train. Nevertheless, the brain worker must not lay the flattering unction to his soul that he possesses a monopoly of mental exertion. Moreover in this as in every case, the personal equation must be considered.

Typhoid Spermatocystitis and Prostatitis.

Few subjects in recent years have occasioned such interest among clinicians and anxiety among sanitarians as has the question of disease "carriers," more especially in reference to the transmission of typhoid fever. Post-typhoid bacilluria is a well-known clinical condition, often occurring as long as five or even ten years after recovery from typhoid fever. The presence of the bacilli in the urine of otherwise healthy individuals is familiar, but their source has been a puzzling mystery. The gall-bladder has long been accused of being a harborer of the organisms, the accusation in many cases having been based upon abundant proof insofar as infection of the feces is concerned. That this organ should be the source of urinary infection is, however, not so easy to understand, especially in the light of the findings of Vyssokovitch that a healthy kidney will not allow the passage of micro-organisms from the blood to the urine, and as in many cases of typhoid bacilluria there is no evidence whatever of a kidney lesion, the searchers for the source of the bacteria have had to turn their attention to the lower urinary tract itself. In the *American Journal of the Medical Sciences* for July, 1910, Marchildon reports the results of some observations made by him in Pick's laboratory in Berlin, which seem to be of considerable interest in this connection. In two patients who died of typhoid fever careful investigation was made of the entire genitourinary system with the result that in one case a purulent infection of the seminal vesicles was found and in the other an acute prostatitis. From both lesions were obtained pure cultures of the typhoid bacillus. Both were men who died during the acute period of the disease, and the findings therefore bear only an inferential relation to the subject of typhoid carriers and post-typhoid bacilluria. In the light, however, of the well-known tendency of these two organs to chronic latent infections with the gonococcus, the suggestion that chronic typhoidal lesions of the spermatocysts and the prostate gland may be causes of bacilluria lasting for months or even years is distinctly worthy of consideration.

Enlargement of the Medical Record.

In accordance with the policy that has animated the Medical Record since its first appearance, forty-four years ago, always to share with its subscribers the benefits which accrue from their increasing numbers, the journal is now once again enlarged. Beginning with the current issue the number of reading pages each week will be increased, and this number will, as heretofore, be exceeded in individual issues when society reports, special articles, or other interesting matter calls for more space. Dating from this issue also the typographical appearance of the journal will be improved, the correspondence will be printed in larger type, and the abstracts from other journals in the department of "Progress of Medical Science" will be more widely spaced and so more easily read. These and other improvements, upon which we need not dwell now but which will, we hope, be apparent to our readers, will all make for a better journal, and the Medical Record will endeavor in the future, as in the past, to continue to merit the interest and loyalty of its many friends, both old and new, who have made these betterments possible.

News of the Week.

Decrease in Typhoid Fever.—The Health Department of the City of New York announces that the number of cases of typhoid fever during the four weeks ending September 17 was much lower than for the corresponding period of last year, the total number for the city being 630, as compared to 924 in 1909. In response to complaints regarding the taste of the city water, the authorities state that this is due to the presence of *Aphanizomenon* in the water, and that the ill flavor will remain until the cold rains come. The water is, nevertheless, quite harmless.

Toadstools for Mushrooms.—Three persons are dead in Orange, N. J., as the result of eating poisonous toadstools which they thought were mushrooms.

Crocker Cancer Fund.—The validity of the bequest made to Columbia University by the late George Crocker, providing that the proceeds of the sale of his house in New York City should, together with the proceeds of the sale of his country place, be used as a fund for the carrying on of work in cancer research in Columbia University, has been questioned by the stepchildren of Mr. Crocker, and the sale of the property has been forbidden until the courts have passed upon the case.

Infantile Paralysis.—In both New York and the District of Columbia the health authorities have classed infantile paralysis with the transmissible diseases and have ordered the quarantine of cases. The Washington Department of Health issued an order on September 20, excluding from attendance at the public schools all pupils who had been within the previous three weeks exposed to acute cases of infantile paralysis. Such pupils will not be allowed to attend school for fourteen days. In New York State the report of all cases and a quarantine for twenty-one days is required. The Commissoner has also issued blanks on which he urges a detailed report of every case occurring since January 1, 1910.

Baths Before Target Practice.—The men of the battleships composing the Atlantic fleet now in southern waters for target practice have been instructed to bathe and make a change of underclothing each morning before the ship goes into action. It is hoped in this way to prevent blood-poisoning through any possible wounds from infected clothing. Such precautions are thought to have been responsible for the absence of cases of blood-poisoning among the men on the Japanese battleships during the Russo-Japanese war.

Typhoid Fever in Toronto.—Typhoid fever is again very prevalent in Toronto. During the latter part of September about 130 persons were under treatment in the five principal hospitals of the city. This is believed to be due to the fact that the city water is infected, probably at the intake. The city filtration and sewage disposal works are progressing somewhat slowly, and considerable dissatisfaction is expressed at the delay in completing these necessary improvements.

Food and Nutrition Charts.—The Department of Agriculture has recently issued a set of fifteen charts on the composition of food materials, which are likely to prove especially useful to instructors and students in classes in physiology and in other branches in which the food and nutrition of man is studied. The charts may be obtained from the Superintendent of Documents, Government Print-

ing Office, Washington, D. C., for $1 for the set. The charts are printed from photolithographs in six colors, and in each case show the protein, fat, carbohydrate, ash, and water contents, and the fuel value expressed in calories. The food materials shown are as follows: 1, whole milk, skim milk, buttermilk, and cream; 2, whole egg, egg (white and yolk), cream cheese, and cottage cheese; 3, lamb chop, pork chop, smoked ham, beefsteak, and dried beef; 4, cod (lean fish), salt cod, oyster, smoked herring, and mackerel (fat fish); 5, olive oil, bacon, beef suet, butter, and lard; 6, corn, wheat, buckwheat, oat, rye, and rice; 7, white bread, whole wheat bread, oat breakfast food (cooked), toasted bread, corn bread, and macaroni; 8, sugar, molasses, stick candy, maple sugar, and honey; 9, parsnip, onion, potato, and celery; 10, shelled bean (fresh), navy bean (dry), string bean (green), and green corn; 11, apple, dried fig; strawberry, and banana; 12, grapes (edible portion), raisins (edible portion), grape juice (unfermented), canned fruit, and fruit jelly; 13, walnut, chestnut, peanut, peanut butter, and cocoanut. Chart 14 gives the functions and uses of food under the headings, "Constituents of Food," and "Uses of Food in the Body." Chart 15 shows the dietary standard for a man in full vigor at moderate muscular work and the estimated amount of mineral matter required per man per day.

Free Esperanto Instruction.—Mr. Arthur Baker, 700 East Fortieth street, Chicago, editor of *Amerika Esperantisto*, writes that he has had prepared 100,000 brief grammars of Esperanto in pamphlet form, and will send one free to any person who is sufficiently interested to ask for it, inclosing a stamp for reply. The grammar has been prepared in order to give every person interested an opportunity to judge for himself regarding the probable value of this international medium of communication.

Medical Inspection of School Children in Toronto.—Medical inspection in the Toronto public schools will shortly be in force. The department of medical inspection is to be placed under the direction of the Board of Inspectors. Dr. Helen MacMarchy has been appointed medical inspector of girls, and Dr. Wilmot A. Graham, medical inspector of boys.

Jewish Consumptive Institute.—This institution, to be used in the treatment of tuberculosis, was opened in Philadelphia on September 11. Addresses were made by the founder, Dr. M. Staller, and by Dr. S. Solis-Cohen, chief of the medical staff. Nurses from the institute will visit the homes of tuberculous patients and instruct their families in the care of the sick. Tents will be provided for sleeping on the roofs in crowded sections.

Marine Hospital Service.—During the last fiscal year 16,766 vessels were inspected by the officers of the United States Public Health and Marine Hospital service. This also meant the inspection of 1,280,000 would-be immigrants, of whom about 30,000 were excluded as unfit, either physically or mentally. The annual cost of the work of the service is about $2,000,000.

Death Rate for 1909.—The mortality statistics prepared by the Bureau of the Census for the registration cities and States of the United States show that the death rate for 1909 was 15 per thousand of estimated population. This is lower than for any previous year of registration and is probably the lowest in the history of the country. The mortality through the year was distributed with more than ordinary uniformity and no epidemics of wide extent occurred. The total number of deaths in the registration area for 1909 was 732,538, of which 54.4 per cent. were of males. The largest number for any single month occurred in March, when there were 70,093. In the majority of the registration States and cities March is the month of greatest mortality, and June of the least.

The official death registration area of the Bureau of the Census includes those States and cities which require registration of a death before the issuance of a burial certificate, and which have complied with other requirements of the Census Bureau. In 1909 the following States were included in this area: California, Colorado, Connecticut, Indiana, Maine, Maryland, Massachusetts, Michigan, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Rhode Island, South Dakota, Vermont, Washington, and Wisconsin. In addition to these returns were received from 54 cities not in the registration States, in which the local ordinances were considered satisfactory. The estimated population of this registration area in 1909 was 48,770,893, or about 55 per cent. of the total estimated population of continental United States.

The Bureau reports 509 deaths during the year from acute anterior poliomyelitis, of which 552 occurred among white persons, and only 17 among colored. There was a somewhat greater incidence of the disease among males, and an increased mortality in August, September, and October. The duration of the illness was reported in only 292 of the cases; in 253, or 87 per cent., this was given as less than one month; in 40 as over one month and less than a year, and in 19 as one year or more. This is the first year for which the statistics of infantile paralysis as a cause of death have been separated. The figures indicate that the disease does not particularly affect large cities of 100,000 population or over.

Pellagra also is a new disease in the mortality statistics. During 1909, 116 deaths from this cause were reported, while in 1908 there were only 23. Previous to this time no deaths were reported from this cause, with the exception of one in 1904.

While the total number of deaths from tuberculosis in the registration area increased from 78,289 in 1908 to 81,720 in 1909, the death rate declined from 173.9 in 1908 to 167.5 per 100,000 of estimated population in 1909. Eleven of the seventeen States for which data are given showed numerical decreases in deaths from tuberculosis in 1909, as compared with 1908, the largest being in New York, 415.

Cancer, on the other hand, showed increases, the death rate being 77 in 1909 and 74.3 in 1908. The actual number of deaths was increased by 4,097.

The typhoid fever death rate which in 1908 was 25.3 per 100,000 of estimated population, the lowest then on record, fell to 22 for 1909. This latter figure is only about one-third of the rate for the five-year period, 1901-1905 (32.2), but it is almost twice as large as the rate for England and Wales.

Pneumonia caused 8,774 more deaths in 1909 than in 1908, the death rate being 143.6 per 100,000, as compared to 136 in 1908. In the number of deaths from influenza there was a decrease of 3,340.

Diseases of the nervous system showed a slight, and diseases of the circulatory system a large in-

crease in the number of deaths for 1909, as compared to previous years. Meningitis gave a lower death rate as well as a numerical decrease.

Gifts to Charities.—The Butler Hospital and the Rhode Island Hospital, both of Providence, R. I., will receive $10,000 each from the estate of the late Mrs. E. A. Shepard of that city. The Butler Hospital will receive further sums also, which are left to it subject to the life interest of another person.

St. Vincent's Hospital, New York, receives a bequest of $1,000 by the will of the late Mrs. Elizabeth Dunleavy.

The National Jewish Hospital for Consumptives at Denver, Colo., receives a bequest of $1,000 in the will of the late J. E. Schoenberg of New York.

Father John A. Kellner, late Rector of St. Gabriel's Church, New Rochelle, N. Y., in his will leaves $2,000 to St. Joseph's Hospital for Consumptives and $1,000 to St. Francis' Hospital, New York.

By the will of the late Amelia P. Rumpf of Philadelphia, the sum of $1,000 is bequeathed to the German Hospital.

The Oregon State Medical Association at its annual meeting on September 9, elected the following officers: *President,* Dr. F. W. Van Dyke of Grants Pass; *First Vice-President,* Dr. R. C. Yenney of Portland; *Second Vice-President,* Dr. S. T. Linklater of Hillsboro; *Third Vice-President,* Dr. R. E. Ringo of Pendleton; *Secretary,* Dr. Calvin S. White of Portland; *Treasurer,* Dr. Edna Timms of Portland. Dr. William House and Dr. N. W. Jones were elected members of the council.

The Washington County (Vermont) Medical Association at its annual meeting on September 13, elected the following officers for the ensuing year: *President,* Dr. L. W. Burbank of Cabot; *Vice-President,* Dr. C. E. Chandler of Montpelier; *Secretary,* Dr. E. A. Colton of Montpelier; *Treasurer,* Dr. L. A. Russlow of Randolph.

The Ohio County (West Virginia) Medical Society at its annual meeting on September 12, elected the following officers: *President,* Dr. William S. Fulton of Wheeling; *Vice-President,* Dr. D. Bigger Best of Wheeling; *Secretary,* Dr. R. J. Hersey of Wheeling; *Treasurer,* Dr. R. M. Baird of Wheeling.

Removals.—Dr. John A. Fordyce has removed to 8 West Seventy-seventh street.

Dr. Walstein M. Tompkins has removed to 158 East 37th street.

Dr. A. E. Palmer has removed to 68 West Eighty-third street.

Dr. G. Carl Huber, formerly of the University of Michigan, has been appointed professor of embryology in the Wistar Institute of Anatomy, Philadelphia.

Captain L. T. LeWald, Medical Corps, U. S. A., has resigned his commission and has been appointed director of the Edward N. Gibbs *x*-Ray Laboratory at the New York University and Bellevue Hospital Medical College, succeeding Dr. E. W. Caldwell. During his service in the Philippines Captain LeWald made a special study of ameba, showing the constant presence of the *Entameba buccalis* in the human mouth and suggesting its connection with certain pathological conditions, particularly Riggs' disease. He also established the use of the Roentgen rays in the routine examination of the heart and lungs of applicants for enlistment in the army.

Mme. Pasteur, widow of Louis Pasteur, died in Paris, France, on September 24, aged 84 years.

Obituary Notes.—Dr. James Donnelly of Toledo, Ohio, a graduate of the department of medicine and surgery of the University of Michigan in the class of 1883, for many years surgeon to the Lake Shore Railroad, and also to the Toledo Fire Department; a member of the American Medical Association, the Ohio State Medical Society, and the Toledo Medical Society; attending surgeon to St. Vincent's Hospital, Toledo for many years, and a prominent citizen highly respected for his upright character and professional ability, died at St. Vincent's Hospital on September 4 of typhoid fever, aged 50 years.

Dr. John P. Phillips of New Haven, Conn., a graduate of the New York Medical College, New York City, in 1859, surgeon in the 11th New York Regiment during the Civil War, died at his home on September 20, aged 77 years.

Dr. William G. Daggett of New Haven, Conn., a graduate of the department of medicine of the University of Pennsylvania in the class of 1884; a member of the American Medical Association and of the Connecticut State and New Haven County Medical societies, and secretary of the New Haven General Hospital Society of Connecticut; attending physician to the New Haven General Hospital, and lecturer in clinical medicine in the Yale Medical School, died at the New Haven General Hospital on September 18, following an operation for appendicitis, aged 50 years.

Dr. Anthony Romig Finck, a graduate of the medical department of the University of Pennsylvania in the class of 1871, died at Philadelphia of pleuropneumonia on September 19, at the age of 77 years. He was for many years one of the consulting physicians to the Masonic Home.

Dr. Gustav Baumgarten of St. Louis, Mo., a graduate of the St. Louis Medical College in the class of 1856; ex-Passed Assistant Surgeon of the United States Navy and a veteran of the Civil War; a member and ex-president of the Association of American Physicians, and professor of the practice of medicine in the medical department of Washington University, died at his home on September 19, after a long illness, aged 73 years.

Dr. William F. Holthausen of Brooklyn, N. Y., was killed in a trolley accident in Indiana on September 24. He was a graduate of the College of Physicians and Surgeons, Columbia University, New York, in the class of 1904. Dr. Holthausen was on his way to Kokomo, Ind., where he was to have been married on the evening of the day he was killed. His brother, a lawyer of Brooklyn, was with him and was also killed.

Dr. Richard K. Macalester of Glenwood Springs, Col., died suddenly in Denver on September 16. Dr. Macalester was born at St. Augustine, Fla., in 1859. Later he lived in Philadelphia and New York. After graduating from the Swiss Polytechnical school, he studied medicine at Heidelberg, Vienna, and Zurich, receiving his medical degree from the latter university in 1890. He lived for a while after graduation in New York City, but went to Glenwood Springs in 1898. Six years ago he suffered a broken leg when thrown from a runabout, when his horse shied at the caravan conducting Col. Roosevelt on a hunting expedition near Glenwood Springs. He has since been in poor health and lived in Denver. Dr. Macalester leaves a widow and four children.

Correspondence.

606 IN SYPHILIS.

To the Editor of the Medical Record:

Sir:—Early last May Dr. Flexner, Director of the Rockefeller Institute for Medical Research, received from Professor Ehrlich a supply of his new preparation, No. 606, for the treatment of syphilis. This remedy up to that time had been used only by a limited number of continental physicians, but the results obtained were so favorable that Dr. Flexner requested my cooperation in its use in a number of cases in the dermatological and venereal wards of the City Hospital. Here, in conjunction with Dr. H. J. Nichols, Captain, Medical Corps, U. S. A., who had previously published some observations on the use of 606 in experimental yaws in animals, we treated fourteen cases during May and June. As experience in the use of the drug at that time had been rather limited the patients were carefully selected as free from cardiac, renal, or ocular disease, in accordance with the contraindications stated by Prof. Ehrlich.

The drug was used in solution at first after the method of Alt and later with Ehrlich's modification of it. Since that time the Wechselmann modification has come into use, which mode of preparation has been employed in subsequent cases. The patients treated at the City Hospital included those with initial lesions, with and without secondary manifestations, early secondary syphilis, as well as tertiary manifestations. Their serum reaction was taken by Dr. Noguchi before and after injection. The most striking effects were seen in a case of chronic scaling syphilis of the palms, of one year's duration, a marked improvement showing at the end of a week, with complete cure at the end of a month. In a case of early malignant syphilis with ulcerative, rupial, and fungating lesions of the face, chest, and arm, the patient showed a perceptible change in a week's time; his general condition improved, he gained in weight, and at the end of five weeks the lesions were completely healed. In another case with multiple chancres of the lips, retrogression of the lesions took place rapidly and by the tenth day all evidence of them had disappeared. A report of these cases will appear in the *Journal of the American Medical Association*, October 1, in an article by Dr. Nichols and myself. This article also embodies a preliminary report on two private patients, one with optic neuritis and another with cerebral syphilis. In the last month I have used the preparation in the following cases:

Case I.—Syphilitic bursitis, affection of the sacroiliac joints and various ulcerative lesions of the skin, the whole forming a picture of malignant syphilis developing within the first year. The patient had been under fairly active mercurial treatment without much result. He was in an extremely cachectic condition so that the remedy was given with a certain amount of hesitation. On September 15, 0.4 gm., prepared according to the Wechselmann method, was injected under his right shoulder blade. On the second day he developed a marked reaction, manifesting itself by rapid action of the heart, his pulse going as high as 130. He had some elevation of temperature, 100.5°, malaise, indefinite pains over the body, was exceedingly nervous, and feared he was going to die. His Wassermann reaction before the injection was ++. At the time of writing the patient is in better physical condition than he has been in months, his appetite is good, his patellar bursitis has improved, and there has been a retrogression of the bone and cutaneous lesions.

Case II.—Latent syphilis with a strongly positive Wassermann reaction. In this case moderate pain developed within ten minutes after the injection was given, extending from the site of the latter down the right arm and hand, and continued until the next morning. Aside from this the man feels as well as he ever did.

Case III.—Double optic neuritis in a patient whose luetic infection dates back seven or eight years. The patient first noted impairment of vision in August, 1909. In March, 1910, a diagnosis of optic atrophy was made and active antisyphilitic treatment instituted. The trouble continued to progress, however, and his Wassermann reaction, September 16, was still strongly positive. In view of this and with the hope of at least arresting the disease, the patient was given on September 19 0.4 gm. 606.

Case IV.—Meningomyelitis. Infection three years ago. In July of this year the patient developed some weakness and loss of control of the left leg, attended by exaggerated knee-jerks and the Babinski sign. The diagnosis of meningomyelitis involving the lateral tracts was made by his attending physician, Dr. Haskell of Bridgeport. The condition improved under large doses of mercury and potassium iodide in a week, and in two weeks the leg was normal. His Wassermann reaction on September 16 was positive and on September 21 he was given 0.5 gm. arsenobenzol. This was followed by very slight pain; no increase in temperature or pulse rate.

These patients are still under observation and a subsequent report regarding them will be made.

In the last three cases the drug was prepared after the latest modified method of Wechselmann, which is as follows: The powder is dissolved in a 10 per cent. solution of caustic soda and reprecipitated with glacial acetic acid; sterile water is then added and enough 1 or 2 per cent. acetic acid to neutralize the suspension. This is then centrifuged, the supernatant fluid pipetted off, and physiological salt solution added. In the cases in which the drug has been used in this manner the pain has been comparatively insignificant. In the majority of those treated, however, a marked swelling took place on the second or third day which persisted for about two weeks and then gradually subsided. About the third day this swelling at times becomes exquisitely sensitive to touch, and pain may manifest itself first at this time.

Of five cases treated at the City Hospital where we have been able to follow the patients, the reaction has remained negative in four up to September 1. In the fifth, one of early syphilis, there is at the present time a marked relapse in the throat and on the penis and scrotum of large moist papules. The injection was given on May 23, 0.3 gm. The reaction became negative on June 10; on September 22 the blood examination showed a marked positive reaction. The man admitted that he had been drinking an excessive amount of alcohol since he left the hospital. If he had been under continuous observation a second dose would have been given as soon as his Wassermann reaction became positive or as soon as a recurrence of the lesions took place. Unfortunately, for the continuous study of a new remedy, it is difficult to keep patients under observation for a sufficiently long time. In all of

the hospital cases the dose given was the original one recommended by Prof. Ehrlich of 0.3 gm., and which later experience has proved to be too small for the majority of cases, a dose of 0.6 and 0.7 gm. not infrequently being administered now. It has been found, too, that the remedy may be safely repeated in from two to four weeks, when the symptoms fail to yield to one dose or when the Herxheimer reaction takes place. It will require observation over a period of several years before we can determine whether one or two or half a dozen doses of 606 will cure syphilis. The results up to this time are truly remarkable in that we have a drug which has a specific effect on the *Treponema pallidum*.

JOHN A. FORDYCE, M.D.

8 WEST SEVENTY-SEVENTH STREET.

CONTROL OF TRIALS OF 606 BY THE NOGUCHI TEST.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—In my preliminary report on Ehrlich-Hata preparation for the cure of syphilis, published in the MEDICAL RECORD of September 24, 1910, I inadvertently omitted to mention that Dr. Noguchi of the Rockefeller Institute made the Wassermann tests according to his modification, and is making the tests in the other cases to be reported later. I believe great importance must be given these careful and delicate tests, for without them the reports would lose much in value.

M. S. KAKELS, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH ASSOCIATION—ARCHBISHOP AND SIR OLIVER LODGE ON SCIENCE AND RELIGION—ROYAL SANITARY INSTITUTE—WOMEN'S SICK AND WOUNDED CONVOY CORPS—INQUESTS—OBITUARY.

LONDON, Sept. 9, 1910.

A SPECIAL service was arranged for Sunday at Sheffield in connection with the British Association when the Archbishop of York addressed the members, contrasting the relations of scientists and theologians at the present time with those which existed in the middle of the 19th century. On the one hand, he said, science has now become aware of its own limitations, and is more conscious than it was of the gaps unbridged, of the mysteries still unexplained, enfolding the ultimate causes of the material world, the origin of life, the meaning of the movements of the human spirit. Materialism as a self-sufficing theory of the universe has become discredited by the best scientific minds. True agnosticism, recognizing the limits of scientific knowledge, has taken the place of that false agnosticism which declared dogmatically that beyond those limits nothing could be known. On the other hand, religion—rather religion thinking itself out, which we call theology—has equally come to recognize its own limitations. Its claim to find in a Personal God the Author and Worker of all things gives it no right to decide the methods of His workings. It proclaims that He, and no mere blind energy, is the Worker, but waits for science to give it the tidings of the way in which He works.

Sir Oliver Lodge gave a lecture in the afternoon at the service of the Sheffield Wesleyan Mission. Referring to the change in our outlook during the last century, he said it was not surprising that many found difficulties in understanding ancient writings, especially in teaching children. Science and literature were not in conflict, but parts of a larger whole. Literature and poetry need not be historically true. At the same time, they might be true to human nature. The truths of science were real, but had nothing final about them. They were stages on the road to human feelings, were more ancient than knowledge, and the instinct of worship was powerful. In this spirit the Old Testament, the greater part of which was manifestly inspired, should be incorporated and understood. As knowledge grew our conception of inspiration might become larger and more definite, but whatever it meant it did not mean infallibility.

On Monday came a descent to the more mundane themes set forth as the program for the week. In the anthropological section the president showed the advances made and appealed for a government grant for the institute devoted to this subject. In other sections there have been many papers and discussions of importance in the several branches of science and of more or less interest—though indirectly—to the profession.

The University of Sheffield conferred several honorary degrees in commemoration of the meeting.

The twenty-fifth annual Congress of the Royal Sanitary Congress was opened on Monday at Brighton. The Mayor welcomed the delegates, numbering over 1,000, at a reception and a luncheon. In the evening the President, Sir John A. Cockburn, delivered his inaugural address, in which he reviewed the growth of sanitary science during the past year. Nothing important in this domain had, he thought, escaped the attention of the Institute, which had become a conning tower from whence the battle of science was directed against disease. The work had spread beyond this kingdom to the other parts of the dominions, and the growth of a common concern was one of the signs of the age. The president enumerated many things which tended to promote disease and the manner in which they should be met, but warned against too hasty generalizations. He was gratified with the Conference of Women on Hygiene, for when women took up a subject they meant business, and victory was not far off. With the advance of interest in the public health there had been an improvement in the status of medical men, and the Medical Officer of Health had been invested with large administrative powers and might be said to have become a high priest of our social salvation.

This is certainly an interesting view of the Medical Officer of Health, and he may be congratulated on his position, but I must beg to interpose that not a few general practitioners are profoundly dissatisfied with the effect on their own status. This very morning I was talking over the condition of the profession with a man who has been practising in one of the best parts of London for many years, and has promoted many forms of sanitation with all his influence, and he assured me that personally it was a losing game, and he knew a number of his confrères had steadily decreasing incomes, which fact they attributed to the growing disposition of the public to look upon the doctor as a State servant. What with midwives, nurses, and other competitors on the one hand, and notification, isolation hospitals, and State provision on the other, they

found it more and more difficult to get reasonable remuneration.

In connection with this congress, Dr. Newsholme, principal medical officer of the Local Government Board, gave an address at the Royal Pavilion on the "National Importance of Child Mortality." He made some home thrusts at some of the authorities, and did not hesitate to assert that negligence and parsimony are to blame for a considerable amount of the differences in mortality rates revealed by statistics. It could not be denied that the rate of increase of the population is falling, and though for the moment we have not reached stagnation, that may arrive within three generations. Infantile mortality is an important element in the national death-rate, and it offers the best opportunity of effecting improvement. The notion put forward by some that infant mortality in slum districts is nature's method of restricting the increase of the unfit was met by the lecturer with an appeal to statistics. There is not much difference in fertility between the classes, and unfitness largely depends on environment. The same influence which caused a high mortality in the first year of life continued its maleficent work right through life. In removing these conditions favoring infantile mortality they were in a very high degree removing those which caused a high mortality in youth and adult age.

Yesterday Sir Wm. Collins took up the subject as at a little later stage of life, and contended that from 5 to 14 the years were becoming not merely educational, but a period for the State handling of childhood. If this were socialism, it arose from the legislation of 1870-'76. The hygiene of childhood he divided into pre-school, school, and post-school hygiene, and referred to the question of heredity. He advocated hospitals for measles and whooping cough, as well as physical exercise in schools, but the last, he held, should not partake of military drill, as that was premature specialization.

Mr. H. Rofe dealt with economy in water supply; Mr. Edgar Newton with sewage pollution of the sea; Mr. Williamson with the state of the Thames, and Mr. W. G. Cooper with the prevalence of child labor as a cause of unfitness in after life.

The Women's Sick and Wounded Convoy Corps have been hard at work in their encampment qualifying themselves to be efficient members of voluntary aid detachments in time of war. About 35 have been out for drill at 7 A.M., and from 9.30 to 11 have been instructed by sergeant-instructors. In the afternoon lectures by medical men have been given. Some of the corps have been entertained on a cruiser.

At the inquest on the doctor who committed suicide, mentioned in my last, a verdict of temporary insanity was returned. It appeared that rumors were circulated to the effect that he did not treat the old gentleman properly, and suspicions were expressed. One person took upon himself or herself to draw police attention to the matter. The post-mortem was conclusive, but the doctor was so affected that he seems to have lost control of himself. The coroner made some scathing comments on the contemptible part of the informer who, sheltered under the refusal of the police to state the name, refused to confess in open court what he had done. Such conduct, he held, everyone would pronounce contemptible.

At an inquest on a death in St. Thomas's Hospital the nurse confessed to having made a mistake in measuring the sleeping draught. The jury found that the patient died from Graves' disease and advanced consumption, but the death was hastened by the overdose of morphia and the treatment for that. The coroner commented on nurses being entrusted to dispense—"for it was dispensing"—and he did not think they should be blamed for misreading hieroglyphics on prescription papers and on measure glasses. The jury agreed with his remarks and said poisons should be given by the doctor himself.

The sudden death of Dr. Benjamin Wainewright, F.R.C.S., Surgeon to Charing Cross Hospital, and the Westminster Ophthalmic Hospital, has taken place at Pontresina, Switzerland, at the age of 57.

Dr. A. J. Alliott, surgeon to Seven Oaks College Hospital and to the Children's Hospital for Hip Disease, has died at the age of 62. He was a Cambridge graduate and a scholar of Pembroke College. He had retired from practice.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 15, 1910.

Present Status of the Treatment of Exophthalmic Goiter.—J. M. Jackson and T. M. Jewett resort to the following measures: Rest the heart and diminish thyroid activity. This includes not only physical but mental rest. The so-called Weir-Mitchell rest cure should be followed in its most absolute form. Drugs in cardiac cases these authors find of little avail. Their best results have followed the use of the neutral hydrobromide of quinine. Five grains may be given in capsule three or four times daily. The acid salt of this remedy is less efficient. The diet must be nourishing and easily digested. Tea and coffee are to be absolutely forbidden or greatly limited. Alcohol and tobacco are interdicted. Bromides may be given to relieve the tachycardia and the nervous symptoms while opium is to be avoided under all circumstances. A favorable statement is made with reference to the Rogers-Beebe serum, although the authors do not give their own results with it. Operation is indicated when the exophthalmos prevents closure of the lids, endangers the eyesight through corneal ulceration, and when three months after good medical treatment there is no marked improvement in the tachycardia, or in general health, or there is an increase in the intoxication by thyroid secretion even though no enlargement of the thyroid gland can be demonstrated. Cardiac cases with beginning impairment of the myocardium should be operated on in order to save the heart, and even where the organ has actually become impaired and the aggravating symptoms are still present operation is indicated to take the strain off the heart and prolong life. Operation should be avoided, if possible, where there is any bronchitis from compression, since it increases the danger of bronchopneumonia, but it is better to operate than run the risk of sudden swelling of the thyroid and a resulting death from compression. The summary of the authors is as follows: Treat medically for three months. Then if no improvement follows, ligate the vessels. If the patient later comes to the operation of partial thyroidectomy, the ligation makes the operation less dangerous. If the goiter is large it is better to remove only the larger lobe and treat the remaining one with the *x*-ray and medical procedures.

Surgical Treatment of Exophthalmic Goiter.—C. A. Porter gives his experience in seventy-two cases and favors surgical rather than medical treatment.

Distortion of the Face and Skull Due to Continued Fixed Posture in Early Infancy.—J. E. Goldthwaite figures seven cases showing how during the early years of infancy the skull can be moulded almost at will.

Some Results of Sanatorium Treatment of Pulmonary Tuberculosis in Children.—H. S. Goodall gives observations on 120 children discharged in the course of six years from the Stony Wold Sanatorium in the Adirondacks. The results have been uniformly good, and he thinks that children should have the same privileges as adults in institutions of the class named.

Congenital Stenosis of the Pylorus: Report of Three Successful Cases Following Gastrojejunostomy; Remarks.—C. L. Scudder contributes the histories of these cases and deprecates the present delay in instituting surgical treatment in such conditions.

Case of Hemorrhage of the Newborn Treated by Direct Transfusion; Recovery.—Clinical history by F. S. Newell. The baby's father acted as donor. Operation was called for on account of vomiting blood twenty-four hours after birth. As soon as the effect of the donor's blood became noticeable the hemorrhage was checked. The small size of the baby's vessels made the surgical technique extremely difficult.

Ovarian Cysts with Twisted Pedicles.—F. W. Johnson reports four cases. All were operated on and all recovered. Full histories are given.

New York Medical Journal, September 18, 1910.

The Surgical Importance of the Omentum.—L. J. Hammond describes the anatomy and physiology of this structure, and then passes on to the pathology, including splanchnoptosis injuries, displacements, and tumors. Of the latter there are the benign and malignant. The former comprise lipoma, which is the most common, fibroma, and myxoma. The latter comprise carcinoma, endothelioma, scirrhus and colloid, and sarcoma. In the last twenty-five years some fifty-five cases have been recorded of torsion of the omentum. Symptoms of these respective conditions are sometimes extremely difficult to interpret. There are no conclusive signs of either tumors or adhesions, says the author, other than a probably movable mass in the former instance, or pain on traction in the latter. Tumors or adhesions at the seat of an operation scar are extremely sensitive. The former are usually freely movable, while in the latter where traction is made which draws the viscera away from the point of attachment intense pain is usually produced. A tumor often suddenly appears. There are usually some gastric symptoms, loss of weight, diarrhea, alternating with constipation, and vague though constant abdominal pain and tenderness; and usually some time in the course of the condition ascites is present in greater or less quantities. The omentum may become cystic, and in rare cases it may undergo calcification within the sac, or sarcoma, carcinoma, or tuberculosis may develop while it is incarcerated.

Duodenal Regurgitation Due to Fatty Foods and Oils as a Clinical Entity; Fat Intolerance of Gastric Origin.—Report of four cases by A. Bassler. None of the patients gave a history of having had a stomach disorder up to the onset of acute symptoms. Physical examination in all was negative.

Notes on a few Prevalent Eye Diseases.—G. W. Vandegrift mentions acute conjunctivitis, trachoma, eczematous keratitis, and myopia. In regard to the first-named he says that at present we are working toward a classification upon a bacteriological basis and applying our laboratory knowledge to clinical conditions as, for instance, the fact that the Morax-Axenfeld diplobacillus is destroyed by solutions of zinc salts which have no appreciable effect upon other forms of conjunctival infections. In trachoma the author says that the final cause has not yet been discovered. There are really two conditions referred to under this head, namely, simple trachoma as found in school children, and succulent trachoma. Each of these diseases is clinically distinct, arising in the conjunctiva as a separate disease and in its entire course differing markedly from the other. In eczematous keratitis, with the corneal ulceration or the phlyctenular conjunctivitis, an eczematous manifestation develops upon the external canthi, the ears, scalp, and anterior nares. The same pathological process is at work in each region, the formation of nodules and their rupture. The bacteriology of the disease is still unsettled.

Acute Intestinal Obstruction Caused by a Foreign Body in the Peritoneal Cavity.—H. Roth reports the finding in the abdominal cavity of a pledget of absorbent cotton originally introduced into the uterus with the intention of producing abortion, an evident perforation of the uterus having been caused, and setting up peritoneal changes resulting in the formation of two adhesions between the loops of ileum and the mesenteric borders. These caused the intestinal obstruction. Abdominal section, recovery.

Important Physical Signs in the Diagnosis of Incipient Pulmonary Tuberculosis.—P. H. Ringer refers to a unilateral shoulder droop, hollowing of the supraclavicular fossa, or its flattening without its becoming hollowed, etc. Palpation should be done with the pulps of two fingers. In percussion importance is attached to a shortening of the note with a heightening of the pitch over one apex. Another sign of value is the expansibility of the bases of the lungs, both in front and behind. The earliest respiratory change noted is granular, rude, or rough breathing.

Aconite.—J. Knott presents a general review of this remedy as given in secular and professional literature.

Heredity.—H. M. Lee discusses this subject mainly from an anatomical standpoint, his sub-headings being evolution, physical form, color, race, man, susceptibility, defects, power of impression in the parent or parents as modifying form, size, or color of brain center of intellect, heredity in regard to disease, susceptibility to disease, immunity, confining remarks to individual men, etc. He closes with a paragraph on environment.

The Syphilitic and Tuberculous Patient.—G. B. Sweeny has experimented with benzoate of mercury in these mixed cases, and also with a mercurialized lymph. Those symptoms due to the syphilis were unmistakably benefited by the lymph, but in no instance did he find the mercurial to modify directly the coexisting tuberculosis.

Journal of the American Medical Association, September 17, 1910.

Proposed Enlarged National Health Organization.—George B. Young suggests a bill designed to embody in law his plan for a national health organization. First, the law should be as brief as possible, and confined to the declaration of certain basic legislative intentions, leaving the details to be arranged by regulations to be promulgated by the President. Second, it should for the present only transfer or consolidate existing or new agencies that are not the subjects of serious dispute on grounds of either expediency or constitutionality. Third, in order to provide for the question of existing activities, the expediency of transferring which is the subject of much dispute, as, for example, certain parts of the Bureau of Animal Industry, Treasury Department, a provision should be inserted authorizing such transfers within one year by Presidential order and providing for a commission or committee of departmental chiefs, or delegated subordinates, who shall advise the President of their findings after investigating each case referred to them, but whose advice shall not be binding on him.

Movable Kidney.—C. A. L. Reed calls attention to the separation of the capsula adiposa from its relations to the abdominal wall to the extent that such relations may have survived the destruction. Special care must be taken

not to separate the capsule from the tunica fibrosa, and he calls attention, as a guide in the operation, to the connective tissue striæ which form the stroma. After removal of the fat from the renal fossa these striæ are divided and the upper segment is attached above the incision and the lower below it, since they are in such intimate connection with the cecum on the right and the sigmoid on the left that they may and probably do become the media of traction by the loaded or replaced bowel on the kidneys and therefore a positive etiological factor in the descent of the kidneys. While the kidney is thus protected from traction, however, care must be taken not to deprive either the cecum or the sigmoid of any suspensory power that may inhere in this arrangement. It is important, therefore, that the lower segment of these striæ shall be attached to the lower margin of the operation wound. Vigorous friction of the tunica fibrosa above the zone covered by the adherent striæ, especially on the posterior surface of the kidney, and carried to the point of inducing punctate hemorrhages, is made in order to provoke an abundant exudate which will cause adhesion to the abdominal wall. Reed does not think that anything further than this is necessary.

Ileocolitis and Acidosis.—T. D. Parke calls attention to this distinctly marked symptom-complex. The symptoms are described as follows: After from one to four days of looseness of the bowels caused by mild ileocolitis, labored breathing develops, often suddenly, followed by prostration, restlessness, obstipation and enlargement of the liver. The temperature is sometimes subnormal. In other cases it stands about 100° F. and in a few patients runs higher. Vomiting with an acetone odor of breath occurs in a good proportion of cases. The urine is limpid and free. Albumin is sometimes found. Urine from three patients was submitted to chemical examination, and in each the report was that ammonia nitrogen was high. Jaundice has always been absent. During the labored breathing the breath feels cold to the hand held in front of the nostrils. This has been interpreted, rightly or wrongly, to mean volatile substances thrown out in the expired air. In fatal cases, death seems to come from exhaustion, from forty-eight to seventy hours after the onset of the labored breathing. In cases of recovery the duration of labored breathing was about the same. Convulsions were not observed and coma not until a few hours before death. The mortality, in a series of thirty-two cases observed, was 71 per cent. In nine cases autopsies were made and the findings were negative as regards gross appearances, except injection of the mucosa of the intestine in some cases and acute yellowish areas on the surface of the liver, extending downward to various depths in the substance. The gall-bladder has in all cases been distended with dark, green, ropy bile. Microscopic examination has only shown fatty degeneration of the liver. Treatment has varied from eliminative to symptomatic, with the employment of strychnine in good doses, epinephrin, and hypodermoclysis of normal salt solution. Treatment is of little avail when sufficient injury has been done to the system, but when this is not the case hypodermoclysis is of value.

Syphilitic Arteritis.—E. M. Hummel says that only recently has sufficient emphasis been placed on the tendency of specific arteritis to appear shortly after primary infection, and on the relative frequency of isolated involvement of the arterial system as a lesion of syphilis. It is now held that this lesion in its pure form practically does not occur in very late syphilis, or more than three years after the initial lesion. The importance of recognition of these facts in the correct diagnosis and treatment of syphilis is sufficiently obvious. As a matter of course, it is essential to interpret correctly the symptoms of diminution of the blood supply, as shown in neurasthenia, transient paresis, etc., not extending to the gravity of organic disease. When actual hemorrhage, softening, or thrombosis occurs, the symptoms are not specially different from those from other causes, excepting the tendency of syphilis to select the branches of the middle cerebral artery for its attacks. In Hummel's experience the involvement of the arteries supplying the striate body, thalamus, and bulb are especially frequent.

Poliomyelitis.—H. E. Robertson and A. J. Chesley report six cases with autopsy. From these they conclude: "1. Acute anterior poliomyelitis is a specific infectious disease characterized pathologically by general toxemia affecting the parenchyma of the heart, liver, and kidneys, and the lymphoid tissues of the body, but spending itself locally on the structures of the spinal cord. 2. Grossly the cord is congested, and on transverse section shows softening and often hemorrhages in the gray matter of the anterior horns. 3. In the cord the infectious agent is located in the perivascular lymph channels of the anterior portions, especially invading the gray matter, but extending to the white matter and pia and occasionally the posterior horns. The brain stem and basal ganglia may be involved. In the cord the medulla and cervical and lumbar swellings are particularly affected. 4. The characteristic lesion consists of collections of cells in the perivascular and pial lymph channels and tissue spaces of the anterior horns. Of these cells the polymorphonuclear leucocytes appear early and are relatively few in number. They are soon displaced by endothelial cells arising from proliferation of the lining endothelium and lymphocytes coming from the blood and lymph streams. 5. Edema of the interstitial tissue and degeneration and destruction of the ganglion cells are always present. 6. The vessels are congested, their walls degenerated, and the capillary branches in the gray matter irregularly distended and often ruptured, giving rise to hemorrhages, which always intensify markedly the amount of destruction. Thrombosis was not observed. 7. Early degeneration of nerve fibers from the anterior roots is a constant feature. 8. Stains for microorganisms were uniformly negative."

Cobweb Brain.—E. L. Hunt reports the case of a girl three years old who had been instrumentally delivered at birth, probably with some injury to the brain, and had afterward suffered from periodical convulsions for a while. She did not talk, sight was impaired, and the general appearance was that of an idiot. An exploratory craniotomy showed a bulging dura mater, which collapsed on incision. The entire right hemisphere of the brain was replaced by a reticulum of cobweb-like tissue filled with clear, watery fluid. No cerebral substance could be seen at the operation and the wound was closed. The autopsy showed practically a complete atrophy of the right hemisphere. The left hemisphere had been converted into a large cystic mass. The basal portions of the brain were well developed and apparently normal.

Infantile Spinal Paralysis.—D. Silver says the objects of operation in infantile poliomyelitis are as follows: First, improvement of form in the paralyzed member by forcible correction (tenotomy, fasciotomy, myotomy, osteotomy, wedge-shaped excision of bone and bone excavation). Second, improvement of function in the nondeformed or corrected member; (*a*) anastomosis, (*b*) restoration of muscle balance by muscle and tendon grafting and transplantation, and (*c*) through securing greater stability in the paralyzed member by arthrodesis, astragalectomy, silk ligaments, tenodesis, fasciodesis, and removal of skin flaps. It is rare to find an untreated patient for whom some benefit cannot be obtained by orthopedic surgery. Fortunately this treatment is most effective in the region most frequently affected, the foot, but in all regions enough can be gained to make the labor worth considering; usually the combination of several operations or procedures will be required.

Sporotrichosis.—R. L. Sutton's patient was a woman, aged thirty, and the lesions were situated on the right arm following an injury by a splinter or sliver in the thumb. Microscopic and cultural tests revealed the sporotrichium, which was developed in pure culture. The patient was treated with potassium iodide with satisfactory results. Sutton notices the differences between the clinical features in some of the French cases and admits the possibility of a difference in the specific organism. An external lesion is not absolutely necessary for the infection, though most cases have such a history. It has been found in a tonsillar crypt and has been produced in the young guinea pig by feeding with infected milk.

Tumors of the Hypophysis.—Dean D. Lewis reports a case of tumor of the hypophysis and discusses the pathology of these growths. He favors the view of association of hypophyseal alterations with acromegaly.

X-Ray Study of Children.—L. A. Levison and H. Dachtler report the results of a study of the use of the *x*-ray in the physical diagnosis of conditions in children. The rays afford a means of controlling such work, which could only otherwise be afforded by autopsies. It has been their aim to check up the physical findings, especially percussion findings, with the *x*-ray, paying especial attention to a number of points concerning which there has been much discussion and uncertainty. They used the teleoroentgenographic method, which recent improvements in apparatus and technique have rendered it possible to use with accuracy and dispatch.

The Lancet, September 10, 1910.

Operation for Prolapse of the Rectum.—L. W. Dryland advises opening of the peritoneum, exposure of the sigmoid and upper part of the rectum, and forcible traction of the prolapsed portion. A flap of peritoneum is firmly stitched to the upper part of the rectum, firm traction being employed to bring this up out of the pelvis as high as possible. The upper portion of the flap is now brought over to the front of the bowel and secured by interrupted silk sutures. Abdomen is closed in the usual way, patient kept in bed for six weeks, the bowels being moved by enema daily for a month. Operation successful in this case when reported twelve weeks later.

Henoch's Purpura with Intussusception.—J. H. Tonking reports one case. The purpuric symptoms lasted some sixteen days before the abdomen gave evidence of intestinal trouble. There was no blood or mucus per rectum. Intussusception reduced through abdominal incision. Recovery.

Aortic Regurgitation in an Infant.—A child aged 18 months was brought to W. A. Young with typical symptoms and signs of aortic regurgitation. Had been pale since birth. The mother had had two attacks of rheumatism, but there was in her no evidence of heart damage, except some accentuation of the pulmonary second sound. Did this child, asks the author, contract endocarditis *in utero* as a result of the rheumatic virus in the mother, or is the case one of congenital morbus cordis, in which the aortic valves are malformed or deficient? The second rheumatic attack occurred in the mother before the child was conceived.

So-Called Chronic Neurasthenia Due to Abdominal Operations; Operation; Recovery.—Case report by P. L. Mummery and E. C. Bridges. The patient was a man of forty-one years, subject to attacks of abdominal pain, and judged to have adhesions resulting from previous inflammations. This view was confirmed by exploratory incision. Freeing of these gave complete relief.

Failure of Nerve Anastomosis in Infantile Palsy.—A. Stoffel says that the failures in this operation are due to (1) engrafting a whole nerve when only a portion would suffice, and (2) the technique of the operation. If a longitudinal section is made into a healthy nerve there is great risk of the knife failing to cut the actual nerve fibers. It may merely separate them and pass into the endoneural connective tissue in the intervals between the nerve bundles. If a nerve is grafted in such a position and comes into contact with connective tissue and not freshened nerve fibers, failure is certain. In general, the author considers the operation as justifiable and worthy of further practice.

Vesicovaginal Fistulæ; A Summary of 21 Operative Cases.—W. C. Bentall analyzes these cases, taking up in order such points as age, number of confinement, days in labor, nature of delivery, days after delivery when urine leaked, time after labor of performance of operation, description of latter, and details of certain cases of special interest. Of the nineteen cases in which the ultimate result was known, in twelve the closure was complete and in seven incomplete.

Enteric Fever Spread by Milk Infection, Probably by Means of a Carrier Case.—H. Stott gives the details of an epidemic in one of the London districts in which a man who was a hostler in a cow stable was probably the medium through which the disease was spread.

Cesarean Section in the Treatment of Eclampsia Gravidarum.—F. J. McCan comments on recent literature on this subject, saying that with present expectant methods the mortality is from 20 to 25 per cent. Modern authorities generally advise early emptying of the uterus. After the first seizure no one can tell what the future will be in regard to further seizures. This intervention has reduced the mortality in Halle and Berlin to 2 or 3 per cent. Rapid delivery had some opponents, but the author says that it may safely be said that termination of pregnancy exerts a more constant and powerful influence on the course of the disease than any other method of treatment yet employed.

The Duty of the General Practitioner to the Deaf Child.—Macleod Yearsley says that it is above all one of prophylaxis. He discusses the relation of the ears to the nose and nasopharynx, the adenoid and tonsil operation, treatment of middle ear disease with and without pain, and also the less common causes of deafness in children, and finally deaf-mutism.

The Value of Blood Pressure Determinations in the Toxemia of Pregnancy.—H. J. Starling says that he is convinced that during the whole period of normal pregnancy the blood pressure is normal, *i. e.* 100 to 120 mm. Hg. He divides all cases of toxemia into two groups. Group one are sthenic in type, with increased blood pressure, which may be detected as early as the third or fourth month of pregnancy, not necessarily preceded by persistent vomiting or marked symptoms common to the first three months, such as slow, strong pulse, enlarging heart, apex beat traveling outwards, diminution in amount of urine passed, percentage of urea only slightly decreased, specific gravity not necessarily low, large amount of albumin in the urine, increasing edema, ending in eclamptic convulsions and death of the fetus. The death of the fetus is apparently due to mechanical causes, *i. e.* the convulsions of the mother. Subsequent to labor, there is a tardy elimination of toxins, often accompanied by albuminuric retinitis and permanent damage to renal and other structures. Group 2 are asthenic in type, much more gradual and insidious in onset, with general malaise and fatigue, increased urinary output with very low specific gravity, slight trace of or no albumin in the urine, no edema or casts, blood pressure slightly raised, due probably to cyanosis, owing to inefficient circulation or not altered, rapid, feeble, or intermittent pulse, finally great prostration and symptoms of profound toxemia. Temporary recovery if fetus dies *in utero* is speedy, and apparently complete recovery after delivery has taken place. In the

first group characterized by high tension we may give complete rest, a carbohydrate diet, free fluids, and thyroid extract in small doses. In the worst cases, or in those seen late we should terminate the pregnancy. In the second group milk diet and carbohydrates should be given, whereas the thyroid extract is injurious. Bicarbonate of soda should be given freely up to alkalinity of the urine.

Central Origin of Some Cases of So-Called Heart-Block.—Commenting on the report of temporary improvement in some cases of Stokes-Adams heart-block, J. F. Goodheart says that he is unable to understand how temporary recovery can take place when the lesion is due to some change in the heart muscle, gummy, fibrotic, fatty or calcareous as the case may be, and consequently he cannot accept the current theory of the cause of all Stokes-Adams disease in every instance. In many instances of patients with cerebral symptoms commonly ascribed to this form of heart lesion the fact is that these people with heart disease never faint. In many of these cases it is difficult to say whether the brain or heart is primarily at fault. He has seen several people in the declining decades of life who have first shown illness by way of the brain, such as vertigo, temporary weakness of one side, loss of consciousness or mumbling speech, who only after such attacks have their hearts shown vagaries of action. Many of the so-called Stokes-Adams cases which recover are really epileptic seizures.

A Case of Chronic Constipation Treated by Faradism of the Large Intestine.—W. J. Burroughs says that there is no need of using a rectal electrode in these cases. Two flattened lead electrodes are adjusted next to the skin over about the middle of the ascending and descending portions of the colon. A Faradic current of about nine volts with an amperage adjusted to requirements of the case is passed for fifteen minutes, then the current reversed and passed in the opposite direction for an equal length of time. The current must have a high degree of penetration, and be capable of a very exaggerated degree of interruption.

Berliner klinische Wochenschrift, Aug. 29, 1910.

Pathogenesis of the Diarrhea of Basedow's Disease.—Balint and Molnar state that this subject has received little attention until in recent years. Our increasing knowledge of internal secretions is responsible for the newly awakened interest. It has been assumed that the diarrhea may be in some way associated with pancreatic insufficiency. The research instituted by the authors is best shown in the relation of a single case, as follows: Women, 27; for past three years exophthalmic goitre. Patient pregnant when disease supervened. Desire for food and drink had been one of the principal symptoms, accompanied by diarrhea. Despite intake of water and food, patient became emaciated. Excess of perspiration was also present. When first examined the patient presented the same syndrome as was shown in the history. The symptoms in any case of Basedow's disease are sufficiently numerous; so that the relation of the case must consist chiefly of the gastroenteric symptoms. The patient, who ate and drank freely, had from four to eight movements daily, either semisolid or fluid. There was considerable fat present, but it was intimately mixed with other stool content. In other words, so-called butter stools were absent. The function of the pancreas was now tested by giving a Boldyreff-Volhard oil breakfast and analyzing ordinary feces as to the presence of trypsin and diastase. The results appeared to show that there was no inactivity in the external secretion of the pancreas. There remains for consideration the recently made claim of Falta that the diarrhea of Basedow's disease is due to insufficience of the pancreatic internal secretion. The authors know too little as to Falta's data to criticize this opinion; but in their own case there was neither diabetes nor experimental alimentary glycosuria.

Two Cases of Tumor of the Medullary Adrenal Substance.—Suzuki, of Prof. Chiari's Pathological Clinic, Strassburg, found two tumors of this nature in 1,000 consecutive autopsies. The first was a chromaffin tumor presenting little interest, as the patient died with a great complication of diseases. The tumor was seated at the right side only, and its existence had no apparent clinical significance, although the gland of the opposite side showed tuberculosis in connection with chronic multiple tuberculous lesions. In the second case the tumor, while occupying the cortex appeared to consist of medullary tissue, or rather of the so-called formative cells which occur in the sympathetic system. The analogy is not complete because the chromaffin bronzing is less constant, while fat cells coexist. The chief significance of this second case, which occurred in a very old woman dead of senile changes, is the relationship of the medullary cells of the adrenals to the so-called large and small sympathetic cells.

Early Symptoms of Tetanus.—Evler, in a serial article on tetanus, discusses first its early symptoms. He cites authorities like Rose and von Leyden. The consensus of view is that trismus must necessarily be present to insure a diagnosis of tetanus. Yet cases are on record in which trimus was absent, although tetanus of the arms, face, and trunk was present. The author finds that the early symptoms of tetanus are transitory, vacillating, alternating. They comprise restlessness, timidity, night terrors, bad dreams, dysuria, dyspnea, etc. The facial expression changes; there may be nosebleed, night sweats, prostration, yawning, vertigo—all symptoms of nervous irritability or prostration. Of more value are certain surgical symptoms. Thus swelling of an extremity, despite high elevation, is suspicious. The member in question may also be hot and painful. Lymphangitis commonly coexists. The blood-pressure is higher on the affected side. The injured limb shows such phenomena as contracture and tremor. Certain muscle groups are in a state of tonic spasm, often latent; that is, spasm appears only upon exertion. (This abstract will be continued with the appearance of the original article.—Ed.)

Münchener medizinische Wochenschrift, Aug. 30, 1910.

Unexpected Good Results from 606.—Duhot of Brussels relates a case in which the mother of a heredosyphilitic child was treated with the Ehrlich-Hata remedy. He has treated 85 cases all told and bears tribute to the general excellence of the remedy. The case cited, while unique in the author's experience, has been paralleled, as was found by communication with Ehrlich himself. This unexpected result was seen in the case of a woman who suffered from a malignant precocious syphilis which proved refractory to vigorous treatment with mercurials and iodides. The local lesions in part suggested a tuberculous infection, but the case reacted negatively to the various tests for that disease. While still suffering from malignant syphilis the patient gave birth to a child with typical heredosyphilis, the roseola appearing very soon after delivery. At a date 18 months after contracting the disease the woman received two injections of the Ehrlich-Hata preparation. There was no immediate thought of benefiting the infant. The apparently incurable ulcers of the mother at once began to heal. By the third day the infant being then three weeks old and suckled by the mother, its own lesions and characteristic aged expression showed improvement, which was progressive until, with the exception of a mild degree of hydrocephalus, the child became quite normal. Cases of this sort show that something unfavorable to the spirochete passes from mother to

child through the milk. Duhot thinks that this substance is an antitoxin, the genesis of which is rendered possible by the use of 606. The author warns against overconfidence, however; believing that spirochetes may lurk in the infantile organism he would give, sooner or later, an injection of the arsenobenzol compound.

Is the Intravenous Injection of 606 Especially Dangerous?—Ehrlich himself answers this question in the negative in response to a record of death reported recently by Fränkel and Grouven. He admits that a supersensitiveness to the remedy may be present in the individual case—in the old manner of speaking an idiosyncrasy. Abundant evidence is cited both from clinical and experimental sources to show that the intravenous injection, rightly carried out, has no particular drawbacks. It is admitted that two deaths have followed intramuscular or subcutaneous injections—these being due to anaphylaxis. In other words the mode of exhibition of so powerful a remedy cuts no figure.

Increase of Rhinoscleroma in East Prussia.—Gerber announces that he was the first to note the presence of this affection in the locality designated (about 1900). He then regarded it as a "platonic" disease. Certain happenings suggested a possible syphilitic origin, but all Wassermann tests proved negative with a single doubtful exception. The author regards this affection as originating in the nose and nasopharynx. From the latter neighborhood it extends readily to the middle ear, causing deafness. It appears to be an error to regard the nose proper as the elective site of the malady. Not only the nose but the throat may be exempt. The nasopharynx is inevitably involved. In many cases the lesions are confined to the nasopharynx and middle ear. As for the disease itself, it still remains a mystery. Many cases of "ozena" are probably due to rhinoscleroma. In addition to the nasopharyngeal localization the subglottic cases must be mentioned. Certain patients suffer chiefly from tracheal symptoms. Intubation is often required, O'Dwyer's tubes being employed. Any attempt to bring rhinoscleroma under the rubric of any known disease seems to be predoomed to failure. It has no necessary connection with tuberculosis, syphilis, or leprosy. There is no doubt that years of study will fix its status as a disease. It must bear a closer relation to ordinary nasal catarrh than has ever been made public.

Deutsche medizinische Wochenschrift, Sept. 1, 1910.

Bacterial Causation of Meat Poisoning.—Bofinger and Dieterlen, army surgeons, discuss the somewhat hackneyed theme of the relationship which exists between ptomaine poisoning and paratyphus infection. As is well known, the lines of demarcation between the simplest food diarrhea on the one hand and the great intestinal germ poisonings—as expressed in such affections as typhoid, cholera, dysentery, etc.—on the other hand are not readily established. Thus a case of apparent ptomaine poisoning turns out to be one of paratyphoid, and there is no doubt that what we understand by food poisoning proves a powerful factor in the genesis of certain specific epidemics of enteric origin. The authors add but little to the sum of our knowledge of these matters. In an outbreak of diarrhea among troops they examined the feces and found a bacterium which responded to all the tests of a true Gärtner bacillus. The cause of the diarrhea lay, doubtless, in a blood pudding which had been commonly consumed by the troops. From the stools was isolated a bacillus which corresponded throughout with the so-called Gärtner microorganism. From the blood pudding was isolated a germ which differed somewhat from the paratyphus B on the one hand and the *Bacillus coli* on the other. Passed through the white mouse the germ behaved like a true Gärtner bacillus.

Potassic Iodide and Arsenic for the Destruction of Typhoid Bacilli.—Tsuzuki and Ishida deal with the subject of the destruction of bacilli in typhoid carriers. Both these medicaments destroy Eberth's bacillus in vitro. But the favorable results obtained on carriers after administering the said substances cannot be set down to any direct bactericidal power. It is a fact that when convalescents are treated with either of the two drugs in question, the bacilli of the disease disappear more rapidly from the urine and feces than in negative control cases. This is a subject readily controlled in practice. It is only necessary to administer the drugs individually to different series of convalescents. It appears further that while potassium iodide gives good results, arsenic gives even better ones.

Bacterium Coli Commune as Pathogenic Germ and Saprophyte.—Fejes, of Prof. Jendrassik's clinic in Budapest, comes to the conclusion, after a study of several cases, that the *B. coli commune* may behave purely as a saprophyte in causing an absorption fever without further pathogenic changes. Naturally so radical a conception requires continuous clinical corroboration. Each typhoid convalescent must be tested as to fecal and urinary constituents. The views of the author are best illustrated by his cases, one of which was as follows: Healthy girl, aged 18, was taken with a severe cold and sore throat, two or three weeks before consultation. From this condition she made a complete recovery. Three days before consultation she was seized suddenly with abdominal pain, chills, fever, constipation, vomiting, and hiccough. Diagnosis: Cholangitis, enlarged liver, right-sided pleurisy. The patient made a good recovery. In order to understand the nature of the condition a bacterioscopic examination was absolutely necessary. The bacillus coli commune was readily cultivated from the blood and found to be highly virulent. The same microorganism was also present in the pleuritic exudate. The author assumes that the B. coli first caused the angina. It was not only swallowed, but also reached the blood. The swallowed germs caused the cholangitis, while those which reached the blood were responsible for the febrile attack. The pleurisy, doubtless, resulted from infection of the germs through the diaphragm. Other cases show a similar mechanism. Such cases of colisepsis bear little analogy with typhoid, but the author believes that such sepsis is often grafted upon typhoid fever, the germs reaching the blood through the intestinal ulcers. Despite the presence of the bacilli in the blood, close observation leaves doubts as to its pathogenicity, i.e., as far as its power to cause metastases is concerned. Instead of colisepis, colitoxemia might be a more acceptable term. In other words, the lesions of the tonsil, gall ducts and pleura were due to local attack, while the blood state was merely a toxemia.

How Should Hereditary Syphilis Be Treated.—Gaucher states that all children of syphilitic parents, although showing no symptoms at birth, are nevertheless infected. The Wassermann reaction has been positive in cases of children of a mother infected during the eighth month of pregnancy. There are two important points in the treatment of these little patients. The first is the feeding. It is doubly important to them to have breast milk, since they need the best of food to give them the necessary strength to resist the disease, and they also obtain from the milk of the infected mother antitoxins that are of value against the disease. It is equally important not to give them to a wet nurse on account of the danger to her of infection. The second point in the treatment is to give mercury by mouth, the sublimate being used in a solution of 1-1000, beginning with a milligram at a dose, and increasing. The effect of the drug is better if fractional doses are used. The author condemns the use of frictions as uncleanly and uncertain, and thinks that the hypodermic use of the drug is unnecessary.—*La Médecine Moderne.*

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery, by Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M.D., LL.D., Albert H. Buck, M.D., of New York City. Complete in Eight Volumes. Profusely Illustrated. Volume Seven. New York: William Wood and Company, 1910.

In this volume the subject of Regional Surgery is continued, the regions treated of being the pelvic and gluteal regions, the extremities, and the abdominal and thoracic cavities. Many of the subjects are of more than purely surgical interest as the diseases treated of are on the borderland between medicine and surgery not yet entirely relinquished by the general practitioner, or "internist." Among these are the neuralgias of the pelvic and gluteal regions, myositis and other diseases of the extremities, and, though a surgeon will never so regard it, appendicitis. An indication of the constant advance of surgery into the territory of the internist is given in the section on surgery of the pericardium, heart, and blood-vessels in which suture of the heart wall and massage of the ventricle are described in a matter-of-fact way.

The volume opens with a well written and comprehensive chapter on "Surgical Diseases and Wounds of the Pelvis and Gluteal Regions," by Charles H. Peck of New York. "The Surgical Diseases of the Extremities" is the title of a chapter written by Charles A. Porter and William C. Quinby of Boston; it does not include all the diseases of these parts, but is rather supplementary to chapters in previous volumes, treating chiefly of the minor disorders of the arms and legs. "Surgical Diseases and Wounds of the Abdominal Wall" are discussed in an excellent but rather brief article by J. D. Griffith of Kansas City, Mo. A brief but instructive article follows, on the "Diagnosis of Tumors of the Abdomen" by Malcolm LaSalle Harris of Chicago, and after this is a chapter on "Abdominal Section" by William McDowell Mastin of Mobile. The section on the "Surgery of the Pericardium, Heart, and Blood-vessels," a thoroughly readable and up-to-date article, is contributed by Robert G. LeConte and Francis T. Stewart of Philadelphia. The section on "Surgical Diseases and Wounds of the Stomach and Esophagus" is written by A. J. Ochsner of Chicago, than whom no better author could have been selected. "Surgical Diseases of the Diaphragm and Subphrenic Abscess" is the subject assigned to J. C. Reeve, Jr., of Dayton, who has done his work well. A chapter on "Surgical Treatment of General Septic Peritonitis" by the late Andrew J. McCosh follows, and the same gifted and lamented author contributed the article on "Inflammatory and Other Diseases of the Vermiform Appendix." "Tuberculous Peritonitis" is well described by Nathan Jacobson of Syracuse, N. Y. This article is followed by one on "Abdominal Hernia" by E. Wyllys Andrews of Chicago, whose description of the operative treatment, especially of his own operation for the radical cure of inguinal hernia, is very clear and interesting. C. W. Oviatt of Oshkosh contributes an article of unusual value on the "Surgical Diseases and Wounds of the Intestines, Omentum, and Mesentery." Last but far from least in point of interest and excellence of treatment is the section on "Surgical Diseases of the Anus and Rectum" by J. P. Tuttle of New York and S. T. Earle of Baltimore.

With its clear print, dull white paper, and wealth of original and beautifully drawn illustrations, this volume makes a very handsome appearance. It is perhaps the handsomest and the most interesting of the series.

Serums, Vaccines and Toxines in Treatment and Diagnosis. By Wm. Cecil Bosanquet, M.A., M.D. Oxon., F.R.C.P. Lond., Assistant Physician to the Charing Cross Hospital, and to the Hospital for Consumption and Diseases of the Chest, Brompton; sometime Fellow of New College, Oxford. And John W. H. Eyre, M.D., M.S. Dunelm, F.R.S. Edin., Bacteriologist to Guy's Hospital and in charge of the Vaccine Department; Bacteriologist to St. Mary's Children's Hospital, Plaitow. Illustrated. Second Edition thoroughly revised. New York: Funk and Wagnalls Company, 1910.

The appearance of a new edition of this work is timely; the subject is of interest to the practitioner because he may here find an aid not only in active treatment, but also in prophylaxis, and in diagnosis. The subject of immunity, upon which the serum and vaccine procedures are largely based, is, unfortunately, very complex; and the student is liable after mastering many theories on the subject to be confronted with a new theory more intricate and abstruse than those which have gone before. Hence the great value of the present book. It is as simple as the subject will allow; it is concise, and authoritative; it is conservative, and fair in its statements; and it is up to date.

Hygiene and Public Health. By B. Arthur Whitlegge, C.B., M.D., B.Sc. Lond., F.R.C.P., D.P.H.; Late County Medical Officer of Health for the West Riding of Yorkshire, Chief Sanitary Officer of the West Riding of Yorkshire Rivers Board, Medical Officer of Health for Nottingham, and Lecturer on Public Health, Charing Cross Hospital Medical School. And George Newman, M.D., D.P.H., F.R.S.E., Lecturer on Public Health at St. Bartholomew's Hospital (University of London); Late Medical Officer of Health of the Metropolitan Borough of Finsbury, Consulting Medical Officer of Health of the Bedfordshire County Council, and Demonstrator of Bacteriology and Infective Diseases in King's College, London. Illustrated. New York: Funk and Wagnalls Company, 1910.

In point of size, this is perhaps the smallest manual on hygiene and public health in the English language; but its value is by no means to be measured by its size, for it is one of the most useful, reliable and complete of the works on these subjects. It is now in its eleventh edition, and it can be recommended as a concise summary of the present-day knowledge concerning public health, as well as a textbook for the student. Unfortunately, the sanitary law, public health regulations, and statistics in general, which take up a considerable part of the volume, are not those of this country. In spite of this one drawback, which is due to the origin of the book, this little manual will prove of value to practitioners and students.

Die Erkrankungen der Flexura Sigmoidea; von Prof. Dr. Th. Rosenheim, Berlin. Halle a. S.: Carl Marhold, Verlagsbuchhandlung, 1910.

This is practically a monograph of 77 pages, forming a section of a volume of a work on digestive diseases by various authors. The author maintains that on account of the peculiar function of the sigmoid flexure its diseases should be considered more or less independently of those of the upper part of the colon. The style is lucid. 17 pages of advertising accompany the book.

Spondylotherapy. Spinal Concussion and the Application of Other Methods to the Spine in the Treatment of Disease. By Albert Abrams, A.M., M.D. (University of Heidelberg), F.R.M.S., Consulting Physician to the Mount Zion and French Hospitals, San Francisco; formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College (Department of Medicine, Leland Stanford Junior University), San Francisco. San Francisco: The Philopolis Press, 1910.

This is not a textbook on osteopathy as a separate therapeutic system, but in an effort to show that spinal therapeutics occupies a legitimate place in medicine. The author has aimed to rescue this subject from the low esteem in which it has unjustly been held and to give it a place befitting its scientific importance. After outlining the history of spondylotherapeutics, the author discusses the anatomical, topographical, and physiological data relating to the spinal column, including the spinal cord and the sympathetic system, then details the symptomatology of the spine, next presents a summary of spinal diseases and their symptoms, and in the following chapter deals with general spondylotherapy, including abdominal supporters, acupuncture, counterirritation, electrotherapy, exercises, reeducation of coordinated movements, spinal hydrotherapy, lumbar puncture, massage, psychrotherapy, thermotherapy, and vibratory massage. The succeeding chapters deal with pseudovisceral diseases, the circulatory system, the respiratory apparatus, the digestive system, miscellaneous reflexes, and the therapeutics and diagnosis of pain. The work represents an unique contribution to medical literature, and in the wealth of its contents, cannot fail to be of distinct value to the general practitioner.

Life and Health. By James Frederick Rogers, M.D., Assistant Instructor Physical Diagnosis, Yale University. Author of "The Body at Its Best" and other essays. Philadelphia and London: J. B. Lippincott Company, 1910.

The writer has evidently avoided the analytical method as far as possible, endeavoring rather to consider structure and function in its entirety by tracing its historical development. In the first part of this volume is presented a general picture of the body in life and health. The second part considers more explicitly hygienic problems under the sections: Internal conditions of health; and external conditions of health. A short index is appended.

Society Reports.

AMERICAN ASSOCIATION OF GENITOURINARY SURGEONS.

Twenty-fourth Annual Meeting Held at Washington, D. C., May 3, 4 and 5, 1910.

The President, Dr. Hugh H. Young of Baltimore, in the Chair.

An Experimental and Clinical Study of the Functional Activity of the Kidneys by Means of Phenolsulphonphthalein.—Dr. John T. Geraghty and Dr. Rowntree of Baltimore read this paper. Their conclusions were as follows: 1. Functional tests considered in conjunction with a careful clinical study of the patient undoubtedly furnished information of decided value regarding the functional capacity of the kidneys. 2. The phenolsulphonephthalein test as used by them had many advantages over all other functional tests so far proposed. 3. Phenolsulphonephthalein itself was better adapted for use as a functional test than any other drug previously employed for the same purpose on account of its early appearance in the urine and the rapidity and completeness of elimination by the kidney. 4. The method of quantitative estimation of the amount of drug excreted was simple and exceedingly accurate. 5. The permeability of the kidney for this drug was decreased in both chronic parenchymatous and chronic interstitial nephritis, the decrease being most marked in the interstitial variety. 6. The test had proven of great practical value in revealing the true renal conditions in cases with prostatic obstruction. It was here of more value than the urinary output, total solids, urea, or total nitrogen, and enabled the surgeon to select a time when the kidneys were in good functional condition. 7. The improvement in cases of prostatic obstruction following the institution of preliminary treatment was strikingly demonstrated by this test and the time most suitable for operation was indicated. 8. In unilateral and bilateral kidney diseases the absolute amount of work done by each kidney as well as the relative proportion could be determined when the urines were obtained separately.

Dr. Hugh H. Young of Baltimore said that earlier than the year 1900 he had worked in Casper's clinic when he brought out his phloridzin method. He had tried the phloridzin test, the freezing test, and quite a number of others, and given them all up, except the ordinary test for urea, the total solids, the amount of water, and a general study of the patient's systemic condition.

Dr. Geraghty said that in conjunction with this test they had carried on a great many of the other functional tests. Indigocarmine had been used because it was most rapidly excreted. They had been taught that indigocarmine exaggerated the lesion, but in a great many cases it would not appear for an hour or two. With phloridzin they had found certain cases that were excreting about half the normal amount of phenolsulphonephthalein in which sugar would not appear at all.

Removal of Papilloma of the Bladder by the High Frequency Current.—Dr. Edward L. Keyes, Jr., of New York read this paper. He presented a very simple apparatus for the intravesical treatment of bladder tumors. The idea of using this instrument for the destruction of neoplasms was by no means new. It had been employed for neoplasms on the surface of the body to a considerable extent and with success. The apparatus consisted of a small insulated cable about the size of a No. 6 ureter catheter, which could be used through any modern cystoscope. This wire was attached to a high frequency current apparatus, introduced into the bladder through the cystoscope, and manipulated therein after the manner of the ureter catheter. He had used the D'Arsonval or double pole current. At first one pole was placed in the bladder and the other in the patient's hand, but recently both poles had been placed in the bladder, tying the two ends together. The wires must be in absolute contact with the tumor. The simplest method was to get as near the base of the tumor as practicable, plunge the wires in, and then turn on the current. The duration of the burning varied with each case. Dr. Keyes reported one case in full of removal of a papilloma of the bladder that had recurred after removal by the suprapubic route.

Dr. Francis S. Watson of Boston said that as the author of the most radical means of dealing with tumors of the bladder, he would most heartily welcome any suggestions which looked towards its being abolished. He did not know what the action of this electric current was, but whatever there was beyond burning we would have to look to for its presumably good results. He did not quite see why cancer of the bladder was materially different from cancer elsewhere. The radical operation to be successful should be done in the early stages, not after the tumor had involved the whole bladder. One should not wait for a tumor of the breast to involve the lung. If it was cancer, one could not do it too early nor too radically. All else was in the line of palliation as far as he could understand it. It must be remembered that these cases of benign papilloma had recurred as late as thirteen years after removal, so that the fact that certain cases might go on after removal of carcinoma with delayed recurrence rendered it very difficult to come to a correct conclusion.

Dr. Louis E. Schmidt of Chicago said all these intravesical methods would probably be only used for palliative treatment, in cases where the patient positively refused to consider a cutting operation. Of course, it was too early to come to a definite conclusion, but in a general way, judging from other intravesical work, he was inclined to believe that the value of this method would not be any greater than those that had been thoroughly tried out.

Dr. Samuel Alexander of New York thought that every man in the Association who had an opinion should express it against this method being used for primary tumors of the bladder which were operable by other means. But in recurrent carcinoma of the bladder, which meant either death or total extirpation of the bladder, we should welcome any experimental work in this direction. He would use palliative means of this sort just as he had used serum therapy. He believed in using all the palliative means in carcinoma of the bladder before adopting the radical measure recommended by Dr. Watson.

Dr. Francis R. Hager of Washington described a method he had recently used in removing carcinoma of the bladder. After a suprapubic incision down to the bladder, a cystoscope was introduced into the bladder, and pins were passed through the bladder wall from the outside through the suprapubic opening, the cystoscope being used to guide him in placing the pins outside the tumor area. The incision into the bladder was then made as indicated by the pins and the operator was thus enabled to know that he was cutting outside the tumor area. In this way the tumor could be removed without cutting or breaking into it in any way.

Dr. Hugh H. Young of Baltimore mentioned his work during the past year with the operative cystoscope which he had shown a year ago. The two principal troubles he had had were the hemorrhage and dealing with the base. In one or two cases the hemorrhage had been rather alarming. It was impossible with any operating cystoscope to destroy the base. Resorcin had been used with good results. Cauteries had recently been added to the instrument for use in the later stages of the operation. He thought the method which Dr. Keyes had used was one of

great promise. A number of men seemed to think this high frequency current had a peculiar selective action on pathological calls.

Dr. KEYES in closing said he thought there were certain parts of the body where we got certain types of malignant growth sufficiently early to remove them by minor means. The part of the body most generally recognized as falling under that classification was the skin. Nitze a long time ago said he could do the same thing in the bladder. Everybody said that Nitze did not follow his cases long enough, but the fact was established that Nitze did by this means remove, temporarily at least, tumors from the bladder. There was just one case known to have gone twenty years without relapse of a bladder tumor after suprapubic operation. If one had to choose between suprapubic operation and an intravesical operation, he would select the palliative measure, the one that would temporarily remove the tumor, with the minimum inconvenience in the patient.

The Diagnosis of Stone in the Pelvic Portion of the Ureter.—Dr. HUGH H. CABOT of Boston read this paper which was illustrated with lantern slides. A stone in the ureter might be invisible by means of the *x*-ray on account of faulty technique, the chemical composition of the stone, its small size, and the position of the stone. This last cause of non-visibility of a calculus in the ureter had been brought very forcibly to his attention recently by two cases. In the first a calcium oxalate stone was found at operation in the ureter at the point where it crossed the iliac vessels, though *x*-ray plates made by an expert had been negative. The stone was then placed upon a skeleton pelvis as nearly as possible in the proper position and an *x*-ray plate taken, which again failed to show the stone. In the second case the *x*-ray was also negative taken in the ordinary way. But by placing an Edebohl's cushion under the patient's loins, placing the tube over the region of the umbilicus, and focusing obliquely downward into the pelvis, the stone was shown. At operation the stone was found lying over the iliac vessels in a position nearly similar to that of the first case.

Dr. JAMES PEDERSEN of New York said that if it were possible to place patients in such a position as to get a direct line through the pelvis, throwing the sacrum out of line, it would be a great help.

Dr. LOUIS E. SCHMIDT of Chicago said that in locating the exact position of the stone it was desirable to have the patient in different positions, but in taking the picture in the first instance it would seem that it was not only desirable to change the position of the patient but also to change the position of the tube in all those cases where a stone in the ureter was suspected.

Dr. HUGH H. YOUNG of Baltimore said he had been experimenting in much the same way, except that he had used the compression diaphragm against the abdomen. The results had been only fairly satisfactory, and it was probably better to do as Dr. Cabot had done

Dr. CABOT said the calculi in his cases were from seven to twelve centimeters above the bladder orifice of the ureter, lying over the thick portion of the sacrum, and he believed them to be invisible in most plates, no matter with what tubes taken. Twenty-eight negative plates had been taken on these two patients, with every known method and every known density of tube. He had tried the sitting position, but it seemed objectionable because it got the tube so near the patient's face. In his method the tube was nearly eighteen inches away from the patient's face.

Summary of Results Reported from the Use of Vaccines and Sera of Gonococci and Other Pyogenic Organisms in Urology.—Dr. R. F. O'NEIL of Boston read this summary, which was based upon ninety general and special articles on vaccine therapy, upon personal communications and personal experience. In gonorrheal infection in general most reports were that a stock vaccine made from a good strain was as serviceable as an autogenous one. In joint infections the autogenous was to be preferred. To have any general application in the treatment of gonorrhea a stock vaccine would have to be employed, for the double reason that the preparation of an autogenous vaccine required time and skill, and in a chronic case it might be very difficult to procure sufficient material to make a good one. The limitations of the doses of the ordinary organisms had been pretty well worked out, so that now the regulation of the amount and frequency of the dosage by the estimation of the opsonic index seemed to be unnecessary, quite as good results being obtained when these were regulated by the clinical symptoms and reaction. The almost universal opinion was that vaccine treatment in acute and chronic urethral gonorrhea, whether a stock or autogenous vaccine had been used, had proved to be of no value. The same applied to antigonococcus serum in urethritis. Apparently favorable results in epididymitis following the use of vaccines and serum had been reported by a few observers, but in most cases the ordinary methods of treatment had been also used, and it was hard to say what rôle the vaccines played in a condition which varied clinically to such an extent as did this disease. In gonorrheal prostatitis and vesiculitis there was very little to show that vaccines were of any benefit, except that some men thought that their cases did better when the vaccine treatment was added. Better results were reported from the use of antigonococcus serum in epididymitis. The reports on the use of gonorrheal vaccines in gonorrheal septicemia were not sufficient upon which to base any definite conclusions. As to the effect of gonococcus vaccines in joint conditions, the author quoted the following statement by Ebright: "The only lesions that respond with sufficient uniformity to put the treatment on a secure plane are the joint lesions." It should be combined with other forms of treatment, and might be regarded as an advance in therapeutics. In infections of the urinary tract with other organisms, and in bacteriuria, the vaccines did not appear to have any beneficial effect.

Vaccine Therapy in Genitourinary Tuberculosis.—Dr. FAXTON E. GARDNER of New York read this paper. There were 83 mentioned or reported cases of renal tuberculosis treated with tuberculin, with 18 called cured, 30 benefited and 25 not improved. To infer that tuberculin cured 21 per cent. of the cases of kidney tuberculosis and improved 36 per cent. more would be at least premature. In fact, there was no conclusion to draw from these cases. The details were thoroughly insufficient in all except 10 of the cases. We could not accept the statement that a case was cured without having some sort of proof. The only proof given in most of the reports was that the patient was in good health and had no more painful symptoms. A symptomatic cure could not be accepted as a real cure in such a disease as renal tuberculosis. There was not in a single report anything concerning the functional value of the kidney supposedly cured. But despite all objections, there remained a few cases in which one could not help thinking that tuberculin had a beneficial action on the kidney lesion, and practically everybody agreed that it had a decidedly favorable action on the general condition. Of 61 cases of tuberculosis of the bladder reported as having been treated with tuburculin, 20 were reported as cured. It seemed well established that tuberculin had a marked effect on the pain and frequency of urination, and also on the amount of pus in the urine. The only conclusion that could be drawn from the literature of tuberculin in genitourinary tuberculosis at the present time was this: Tuberculin raises the natural defensive power of the body. Whenever the defensive power is normally sufficient to cope with the morbid process, the reinforcement it receives from tuberculin is useful; in disease where the natural defense is unable to overcome the tuberculous process, it is very doubtful

whether tuberculin can raise it to a point where it would be able to effect a spontaneous cure. When tuberculin is presented as a curative agent, it may be eyed with suspicion; when as an adjunct to a normally conservative treatment, it should be welcomed.

A Further Report on Antigonococcic Serum and Antigonococcic Bacterins.—Dr. GEORGE K. SWINBURNE of New York said that in the work he had done during the past year he saw no reason for changing the opinion that he had expressed a year ago, namely, that acute complications were given prompt relief by the serum and that it acted in almost all those cases as a specific. Its action had been marked in cases of acute gonorrheal rheumatism occurring in primary attacks, and it certainly continued to act as a specific in these cases. As a working rule he preferred to use the serum first and then continue treatment later with the bacterins. Some cases did well with the bacterins and not so well with the serum, and *vice versa*.

Clinical Report of Cases Treated with Gonorrheal Vaccines and Cases Treated with Antigonococcic Serum, with Reference to Joint Affections, with Remarks and Conclusions.—Dr. LOUIS E. SCHMIDT of Chicago drew the following conclusions: 1. The site of injection with either a vaccine or a serum was of no importance as to therapeutic action—yet on account of local symptoms that might arise the deep or intramuscular mode of administration, paraticularly into the gluteal region, was both the most desirable mode and place for the injections. 2. That the technique to follow was the one which required strict asepsis. 3. That satisfactory results had been noted with the use of serum as well as with vaccine in the various kinds of cases. 4. Antigonococcic serum seemed to be used to greatest advantage in acute or subacute gonorrheal toxemia cases—those cases which were so often referred to as "gonorrheal rheumatism." That serum was of no practical value in the inveterate, long-standing cases. 5. That the vaccine mode of therapy had shown satisfactory results in some true gonorrheal arthritic conditions—where undoubted metastatic conditions were present and where a gonococcemia was probably present. In the very acute attacks some especially good results were noted. 6. That serum therapy had been of no distinct value in non-metastatic or toxemic conditions—that vaccines were to be used in these conditions. 7. As to the dosage of serum, that it was desirable to commence with small dosages, as 2 c.c., to repeat or even to increase to 4 c.c. on the second or third day. If no improvement was noted, to increase to 6 or even 8 c.c., to be given every fifth day. In general, the smaller the dose the more quickly could it be repeated; the larger the dose the greater the interval between injections. The large majority of cases required 30 to 50 c.c. of serum. 8. That the dosages of the vaccine must vary as to the case—that comparatively small doses, 10 to 30 million bacteria for the acute gonorrheal joints, was usually sufficient. In the subacute or chronic cases 50 to 100 million bacteria generally gave the best results. In both instances he was inclined to believe that the best results were noted when injections were given about five days apart.

Results Obtained by Autogenous Vaccines in Various Urinary Infections.—Dr. JOHN T. GERAGHTY of Baltimore gave his results in 14 cases. Four were renal infections due to the colon bacillus. Six were cases of mild cystitis. Three of these were due to the colon bacillus, 1 to the *Bacillus lactis aerogenes*, 1 to the *Staphylococcus albus*, and 1 to the colon bacillus and *Staphylococcus albus* combined. There were 4 cases of bacteriuria, in 2 of which the *Micrococcus ureæ* was found in pure culture, in 1 the *Staphylococcus albus* was found in pure culture, and in 1 the *Micrococcus ureæ* and the colon bacillus were found combined.

These were all cases that had resisted other forms of treatment and had been under observation a long time. All of the patients were treated over long periods of time, the majority over six months. An autogenous vaccine was prepared in each case, and doses from 100 to 800 million were employed. No reaction whatsoever was noted from the large doses. In not a single instance was any improvement produced which could in any way be attributed to the vaccines employed.

A Report of the Results in Certain Forms of Genitourinary Diseases Treated with Vaccines.—Dr. JOHN H. CUNNINGHAM, JR., of Boston read this paper. In gonorrheal infections both stock and autogenous vaccines had been used, the dose in the acute febrile cases varying from 2½ to 10 million, and in the chronic cases from 10 to 75 million. The doses had been gradually increased, and had been given at intervals of from one to seven days, oftener with the small doses and at longer intervals with the large doses. In gonorrheal rheumatism the vaccines did not appear to have shortened the febrile period, but the patients were possibly more comfortable. In the postfebrile cases almost immediate alleviation of symptoms after the first dose or two was generally noted. Functionating but not always normal joints had been obtained. From 10 cases of gonorrheal rheumatism treated with antigonococcic serum the only deduction that could be drawn was that little or no benefit might be expected, but an occasional brilliant result might be obtained. In four cases of chronic gonorrheal prostatitis and seminal vesiculitis the vaccines did not produce any beneficial results. In *Bacillus coli* infections associated with tuberculosis vaccines proved beneficial, as evidenced by some diminution in the symptoms of frequent urination, pain, and the degree of cloudiness of the urine. In only one case, however, did the colon bacilli entirely disappear from the urine. A predominating colon infection of the bladder and renal pelvis, if of long duration, might temporarily improve during the employment of vaccines, but it had not appeared to produce any permanent improvement in the condition of the urine in the cases that had been followed.

In genitourinary tuberculosis, the author said, the doses should be very small. An initial dose of 1/50,000 mg. R. E. solid substance might be given, and the dose very gradually increased to 1/15,000 mg. No reaction should occur. Theoretically and practically, the indications for the use of vaccine in chronic localized tuberculosis, when surgical conditions had been efficiently met and cure was not forthcoming, were hopeful, and the vaccine should be employed until further data established its value more precisely.

Value of Vaccines in the Treatment of Infections of the Urinary Tract.—Dr. HUGH CABOT of Boston read this paper. This report did not include tuberculous and gonorrheal infections. The author's conclusions were as follows:

1. The use of vaccines was followed by improvement of the symptoms in more than half the cases. 2. Vaccines had little effect on the bacteriuria. 3. The results were practically the same whether the lesion was in the upper or the lower urinary tract.

Two Cases of Renovesical Tuberculosis Treated with the Bacillus Emulsion.—Dr. JAMES PEDERSEN of New York reported in detail two cases of renovesical tuberculosis treated with bacillus emulsion with good results.

Results Obtained by the Use of Tuberculin in Genitourinary Tuberculosis.—Dr. HUGH H. YOUNG of Baltimore reported seven cases in which accurate records of the condition before, during, and after the treatment had been preserved. This was too small a number, Dr. Young said, to permit of accurate conclusions being drawn, but he thought it well to present the records so that they might be accessible to others in collecting a long series of well-observed cases.

Dr. Hugh Cabot of Boston said that in his opinion tuberculin should be confined to cases which were inoperable and those in which operation had been done; that it should not be used as a substitute for operation. In tuberculosis of the epididymis and the vas the tuberculous focus should be removed and then tuberculin treatment started. The same in tuberculosis of the kidney. He had never seen a healed tuberculous kidney.

Dr. Louis E. Schmidt of Chicago agreed with everything Dr. Cabot had said except with regard to the healed tuberculous kidney. He had repeatedly seen specimens in different pathological laboratories shown as cured tuberculous kidneys.

Dr. Francis R. Hagner of Washington said he had seen the symptoms increase very markedly from small doses of tuberculin after removal of the kidney.

Dr. John T. Geraghty of Baltimore said from his experience with tuberculin it had been impossible to draw any conclusion so far. He was inclined to agree with Dr. Cabot as to when it should be used. He had only had one case that seemed to do badly under tuberculin. All the other cases had shown improvement.

Dr. James Pedersen of New York thought the question of tuberculin treatment would reduce itself to a selection of cases. In his second case there was an apparent cure of two years' standing.

Dr. Schmidt said his experience with vaccines in colon infections of the urinary tract covered nine or ten cases. All had been treated with stock vaccines. No urine had cleared up under the vaccines, though there had been some improvement as regards urinary symptoms.

Dr. H. A. Fowler of Washington mentioned a case of pyelitis in which the infective organism was the pneumobacillus of Friedlander. A vaccine was made and the patient was given doses ranging from 100 to 500 million. His symptoms had improved very markedly, but the urine had not cleared up.

Dr. Edward L. Keyes, Jr., of New York said it had been his practice in tuberculosis of the kidney to remove the kidney if that was permitted, and subsequent to operation not to use vaccines unless the patient was not spontaneously improving in his vesical symptoms or in his general weight. In the seven cases in which he had used vaccines following nephrectomy it had seemed to him that the vaccines did good at a time when the patient was not spontaneously doing well.

Dr. Edward Martin of Philadelphia said he saw no difference between the results obtained by this vaccine treatment and those obtained by other methods. He had been astonished at the freedom and carelessness with which this method of treatment had been used. The vaccines were often administered by men who had not the very faintest knowledge of their therapeutic effect or of their possible dangers.

Dr. Alfred T. Osgood of New York said that in his hands the vaccines for colon bacillus infections and for the pyogenic infections of the urinary tract had shown absolutely no good results. He had never seen a colon bacilluria clear up. As to tuberculosis, he agreed with what had been said by Dr. Cabot and Dr. Keyes.

Dr. Young said he wanted to indorse very thoroughly what had been said by Dr. Cabot, Dr. Keyes, and Dr. Schmidt in regard to the operative treatment, and he hoped his paper would be taken merely as a collection of apparently favorable cases for tuberculin.

Officers.—The following were elected for the ensuing year: *President,* Dr. Charles L. Gibson of New York; *Vice-President,* Dr. Edward Martin of Philadelphia; *Secretary and Treasurer,* Dr. Edward L. Keyes, Jr., of New York; *Member of Council,* Dr. H. E. Squiers of New York.

Place of meeting next year, New York City.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 19, 1910.

Dr. C. N. B. Camac in the Chair.

Preliminary Report on Sahli's Desmoid Test.—Dr. N. B. Potter said that he wished it understood that this was merely a preliminary report which had been undertaken for the purpose of investigating Dr. Sahli's test. The methylene blue pills were made according to Sahli's formula. They had made the tests in all sorts of diseases and in some normal individuals; sixty tests were made upon 38 normal individuals. Where digestion was normal the reaction showed itself in about two hours; when the reaction did not appear until after four hours it was considered delayed, and where it did not occur for twelve hours or longer it was considered negative. Of these 60 tests, 43 were positive, 10 delayed, and 7 negative. In one series of tests 7 tests were made upon 6 individuals with 7 positive reactions; 26 tests were made upon 16 individuals having hyperacidity where there were 19 positive reactions, 4 delayed, and 3 negative reactions; 4 tests made upon 3 individuals having hypoacidity gave 3 positive and 1 delayed reaction; 12 tests made upon 6 individuals having anacidity gave 6 positive and 6 delayed reactions. In severe cases two or more tests were made and results were quite uniform. In all 74 tests were made upon 30 individuals of which 48 were positive, 12 delayed, and 14 negative. In pernicious anemia, afterwards confirmed by autopsy, there were 6 tests upon 3 cases, all of which were negative. Three tests were made in one case of secondary anemia of which one was positive and two negative. In one case of moderately severe secondary anemia, one test was made which was positive. In one case of gastric carcinoma one test was made which was positive. Their results agreed very closely with those obtained by Dr. Sahli.

Dr. C. G. L. Wolf said that the claims of Sahli's test rested on a sound physiological basis. When the indicator was given with a regular meal the action of the gastric juices was much more physiological than when given with a test meal. The type of meal had a distinct effect upon the type of secretion, therefore the secretion following a test meal of weak tea or rusk was not to be compared with that following the ingestion of an ordinary full meal. The only indicator that could be relied upon was one that could be given with a full meal. Sahli protested that the usual tests for hydrochloric acid and pepsin were not reliable. This test ingestion deserved greater consideration.

Aneurysm of the Aorta, with Important Clinical Symptoms.—Dr. R. G. Snyder gave a lantern slide exhibition, showing the special features in several cases of aortic aneurysm. The first specimen was from a man who gave no history of syphilis. The aneurysm was just above the aortic valve and ruptured through into the left pleural cavity. The second specimen was from a man supposed to have tertiary syphilis. The aneurysm ruptured into the trachea and at autopsy an acute syphilitic ulcer was found at the seat of the aneurysm. Another slide showed an aneurysm which simulated a tumor. There was no murmur and a diagnosis of tumor had been held for some time, but as there was no glandular enlargement nor other symptoms of tumor, it was supposed that an aneurysm existed. The death of the patient and the autopsy findings confirmed the diagnosis of aneurysm. In another case of a man coming into the hospital six months after having received an injury, the face, hands, and neck were blue. His wife had noted the blue color several weeks before. There was a systolic murmur and perforation into the superior vena cava occurred later. For two weeks before his death a thrill could not be felt in the left arm. At

autopsy a thrombus was found. The specimen illustrated very clearly the adhesions and pressure conditions. A case of Dr. Camac's showed two areas of dullness, one in the back between the left scapula and the spine and another to the left of the sternum in front. The heart was not much displaced. There was pressure both on the sternum and on the ribs behind. It was thought that possibly the man had two aneurysms. The autopsy confirmed this suspicion. In addition to the two aneurysms there was an aortic incompetency. A clot removed from one of the aneurysms weiged 650 grams. There was an erosion of the spine and of the ribs; the spinal cord was also eroded but the man had no myelitis.

Dr. B. Mann told of a case that had come to his service at the City Hospital in which the most marked symptom was a profuse bronchorrhea and a cough. There was an enlargement at the sternoclavicular junction and it was decided that the man was suffering from an aneurysm of the right innominate artery. He was operated upon and died. At autopsy it was found that the aneurysm had started at the arch and pointed out over the sternoclavicular junction.

Dr. Achilles Rose said that before the discovery of the *x*-ray it was almost impossible to diagnose these aneurysms, as the only symptom that was constant was intercostal neuralgia. A number of years ago he had had a patient with a history of syphilis and intercostal neuralgia, upon whom antisyphilitic treatment had no effect. The man died very suddenly and an aneurysm was found at autopsy. In a second case which he had under his care some fifteen years ago, and in which he could not make a satisfactory physical diagnosis although there was a history of syphilis, specific treatment was of no avail. This man also died suddenly of aneurysm. In a third case there was also a history of syphilis and an aneurysm of the descending arch could be readily made out in the scapular region. In this case there was the usual neuralgia but very little disturbance so far as the heart was concerned. There was a slight murmur. This patient died of rupture into the left pleural cavity. Dr. Rose had at present two cases under treatment. One a man 45 years of age in whom syphilis could be excluded; he had, however, driven fast horses and that might have had something to do with the causation. The other case was in a woman, 62 years of age, who had been under observation for three years. Her condition remained stationary. There was marked lateral curvature of the spine that might have dislocated the thoracic viscera thus giving rise to the condition. The diagnosis in this case had been confirmed by the *x*-ray. It was absolutely necessary that these patients should be kept in bed until all unpleasant symptoms subsided. He did not believe in large doses of potassium iodide and never gave more than 10 or 15 grains three times a day.

A Case of Diffuse Sclerosis of the Superficial Veins.—Dr. Harlow Brooks reported this case, which was of peculiar interest because it occurred in an individual very young for any form of venous sclerosis to develop, and especially because of the clear selective tendency manifested in the case for the veins of peripheral distribution with no evidence of other venous or of arterial involvement. He believed the selective tendency was no less frequent in sclerosis of the veins than in arteriosclerosis. It was often quite as evident and even more suggestive and striking since the general veins were so much less liable than the arteries to this type of lesion. The patient was a well formed, rather sparsely built, boy of eighteen years. He entered the City Hospital complaining of pain in the left leg and thigh so severe that he was unable to walk. His family history was negative and he had never done heavy physical work or exercise. He had been a healthy child with the exception of a slight attack of pneumonia and several attacks of tonsillitis and pharyngitis. There was no history of previous disease nor of venous disturbance. Recently he had used alcohol very moderately. On examination he was found to show a complete thrombosis of the left internal saphenous vein extending from 8 cm. below Poupart's ligament down to the ankle. The course of the vein was marked by a hard cord bordered on either side by an indurated and tender red band. There was considerable edema and he suffered intense pain on movement. A circular point of sharply localized bluish discoloration was found over the vein just below the knee joint, evidently a gangrenous area. There were no other lesions of importance demonstrable except that the superficial veins of the entire body, notably those of the extremities, were prominent and palpably thickened. The hands were cyanosed and soon became edematous if allowed to hang down. Moderate exertion caused facial cyanosis. An examination of the heart revealed nothing of importance; no arterial thickening could be made out and there was no change apparent in the retinal vessels. The blood chart showed on admission a systolic pressure of 120 mm., which subsequently went up while the patient was in bed to 140 mm. The temperature varied somewhat but was mostly at the normal level. The urine was normal throughout. The blood examination showed little of importance and varied but little since he had been under observation. The coagulation time was considerably below normal, and the blood cultures were negative. The leg was wrapped in cotton and moistened with 33 per cent. alcohol, and citric acid and potassium iodide administered internally. The gangrenous spot sloughed out, the perforation quickly granulated and there was rapid absorption of the clot in the thrombosed vein. Up to the time of his discharge the circulation was not fully re-established through it. The patient left the hospital after three weeks, walking and apparently well except for the thickened veins. With no other evidence at hand it seemed most likly that this selective venous sclerosis was induced by syphilitic infection either congenital or early contracted. However no evidence could be advanced in support of the accuracy of this diagnosis. They knew that in syphilitic arteritis this selective tendency toward the involvement of certain specific vascular distributions had been well established and it might with equal force be directed to the explanation of this unusual case of diffuse superficial venous sclerosis.

Throat Symptoms the Initial Feature in Three Typhoid Fever Cases.—Dr. N. B. Potter said that a few years ago a case had come to him, having mucous patches in the throat, and he at once suspected syphilis and began treatment. In the course of a few days the patient developed typhoid fever. The second case was of a woman who came to the hospital last fall. She had passed through the hands of four physicians before he had seen her and in each instance a diagnosis of syphilis had been made. She developed typhoid fever with subsequent perforation, was operated upon, and cured. The third case occurred in the French Hospital and it was thought from the appearance of the throat that the patient had diphtheria, but a blood culture showed it to be a case of typhoid. At the time that Dr. Potter decided to report these cases he thought throat symptoms uncommon, but a search of literature had convinced him that they were quite common. Sometimes there were mucous patches and sometimes patches resembling diphtheria on the post-faucial pillar which could be wiped off easily. They did not seem to affect the course of the fever.

Dr. E. Lipman, in discussing these cases, said that throat symptoms were of great value in diagnosis. Occasionally one could come to a conclusion by the aid of these symptoms even before a positive Widal reaction could be obtained. These lesions were quite characteristic of typhoid.

Dr. C. N. Potter said that these patches were found in other conditions, that he had learned of a case of pleurisy and one of angina in which they were present.

Tricuspid Regurgitation with Unusual Tracings.—Dr. B. Mann presented the clinical side of this case. The patient was a man, 43 years of age, who came into Dr. Camac's service in the City Hospital on January 20. He was very short of breath and had a severe, hacking cough. His history showed that he had been a heavy drinker and a hard worker. He had had scarlet fever when a boy and typhoid fever later. His family history was negative. He had been in the City Hospital before and his case had been diagnosed as one of mitral insufficiency; he had also been in Bellevue for the same complaint. His present illness had lasted for several weeks before his admission. At the time of admission he was dyspneic and cyanotic. His neck was full and the veins pulsating and there was a constant, brassy cough. The posterior bases of the lungs were dull and there seemed to be some fluid present. There was dullness in the precordium at the sixth interspace and two inches to the right of the fourth costal cartilage. The pulsations were from 140 to 150, which made it difficult to make out the murmurs. However, there were murmurs in the mitral and tricuspid areas. The abdomen was full and tense and there were systolic pulsations of the liver expansile in character. He was edematous from the waist down; the legs were blue, pigmented, and very edematous. There was a thrill in the radial, posterior tibial, and femoral veins heard on auscultation as a high-pitched bruit. Dr. Camac had had Dr. Bailey make tracings in this case. Pulsations in the peripheral veins were due to three causes, a contiguous artery, junction with an artery varix, or impulse carried through the vessels to the peripheral veins.

The Diagnosis and Treatment of Chronic Gonorrheal Arthritis.—Dr. Charles C. Ransom read this paper, in which he stated that the recent work of Nichols and Richardson on the nontuberculous diseases of the joints had shown the similarity of the lesions in all forms of arthritis. This work had also shown the futility of attempting a diagnosis from the appearance of the joints or from the existing pathological lesions alone, hence in order to make a diagnosis it was necessary to direct their attention more closely to the clinical history of these affections and to their etiology. While gonorrheal arthritis as a complication of gonorrhea did not occur very frequently, occurring in only two per cent. of all cases according to Fournier and Jullien, as a form of infectious arthritis it was quite common. It might affect any articulation even the articulation of the cervical vertebræ and the articular surfaces between the greater and lesser cornua of the hyoid bone. Dr. Ransom had recently seen a case in which the arthritis began in the temporomaxillary articulation. It might also affect the bursæ. The chronic form was almost invariably polyarticular, although the acute form was monoarticular in about 40 per cent. of the cases. From the joint changes alone it was impossible to say what the causative factor of the disease might be. Of course where there was a direct history of gonorrheal infection accompanied or immediately followed by an acute arthritis, persisting long after the urethritis had disappeared, the diagnosis was evident, but frequently it was so remote that there did not seem to be any relation between the gonorrhea and the arthritis. There was a method, however, which gave positive information in the vast majority of instances even of the obscure cases of long standing, which was employed as a routine at the City Hospital. This was the endoscopic examination of the urethra for erosions or ulcerations. These lesions occurred for the most part in the anterior urethra, though they were occasionally found in the posterior urethra and in a few instances the focus of infection existed in the seminal vesicles alone. These lesions were recognized as denuded granular patches, deeply red in color, which bled readily when touched. The lesion in the seminal vesicles was recognized by the thickened sclerosed condition of the vesicles on palpation. The possibility of an arthritis being indefinitely continued by the toxin from an infected focus remotely situated and in itself giving no symptoms was conceded, he believed, by all. Instances in which chronic processes in the joints were arrested by the removal of the tonsils and others in which the joint conditions were cured by the healing of the erosions in the urethra justified such a conclusion. The treatment obviously consisted in healing the erosions. For this purpose he used a 10 to 20 per cent. solution of nitrate of silver every fifth day. Urethral discharges were treated in the usual way. In order to give a better idea of the value of this treatment Dr. Ransom cited a typical case in which a complete cure was effected. While one could in the vast majority of cases in the male reach a positive diagnosis of gonorrheal arthritis by the method described it was obviously not possible to locate the focus of infection in the majority of female cases. In the search for a method which would give definite information a series of observations were carried out to determine whether gonorrheal vaccines would produce definite reactions in all such cases. The results of the experiments were shown upon a chart. There were ten cases in all. In only one case of gonorrheal arthritis was there any elevation of temperature; this was two hours after the injection when the temperature went to 100.6° and reached the highest point four hours after the injection when it was 100.8°. As these cases frequently had a slight elevation of temperature with an exacerbation of the joint trouble, and as none of the other cases showed a similar rise, they were not justified in attributing the rise of temperature to the vaccine. The reaction was not distinctive enough for a diagnosis.

Dr. George Reese Satterlee spoke of his work with the gonococcus vaccines where he had noted that the reaction was accompanied by very little change in the leucocyte count, but by most marked pain in the joints. He had started with injections of 20, then 50, and later 150 million dead gonococci, and reactions had been extremely well marked. Though no cultures were taken from the joints, the pain was probably caused by toxins produced and not by the gonococci themselves. In old cases there were probably no gonococci present in the joints.

Multiple Noninflammatory Necroses of the Liver, with Jaundice, in Chronic Cyanosis of the Liver.—Dr. Horst Oertel of the Russell Sage Institute of Pathology presented a liver derived from a young man, 25 years of age, who entered Dr. Potter's service, at the City Hospital on December 3, 1909, with typical symptoms of mitral stenosis and evidences of general stasis. These symptoms became aggravated and he rapidly developed considerable edema, fluid in the chest, pulsating veins, and pulsating and distinctly enlarged liver. On October 8 there was observed for the first time faint jaundice; his leucocyte count was 8,400. On October 11 the jaundice had become marked with occasional vomiting of brown fluid. The stools were formed, brown, and contained some blood. On October 13 there was epistaxis, and considerable blood in his sputum. On October 16 his jaundice deepened; hemorrhage occurred from the bowels. The stools were loose, yellowish, and contained mucus. He rapidly became weaker and died on October 18. The clinical diagnosis was mitral stenosis, general stasis, with doubtful infectious cholangitis. The autopsy disclosed a mitral stenosis due to fibrous and vegetative endocarditis with relative triscuspid insufficiency, slight hypertrophy of the left, and marked hypertrophy and dilatation of the right side of the heart. The other valves were well preserved. There was a double hydrothorax. Emphysema

and edema of the lungs with numerous infarctions were present. The abdominal cavity contained a liter of dark, reddish brown fluid. The liver came to the costal margin. There was slight distention of the gall-bladder with a few adhesions around the common duct. The liver itself weighed 1,000 gms. and measured 23 cm x 12 cm. It was smooth, and distinctly deeply greenish jaundiced. On section it cut relatively easily. Its cut surface was smooth, and while the normal markings had entirely disappeared, it showed a distinct pattern of hemorrhagic spots and streaks on a distinctly greenish ground color. In places, the hemorrhagic markings were obliterated, or at least much lessened, by a uniform pale greenish color. Microscopical examination showed a lesion entirely distinct from the result of uncomplicated stasis. The lobular structure had disappeared and given way to an irregular, streaky, central necrosis and fatty metamorphosis leading to disorganization of the liver lobules. The central veins were dilated; their walls frequently hyaline and swollen. Immediately surrounding them the liver tissue was necrotic with remnants of liver cells, frequently still lying within the reticulum, much free blood, some bile pigment, and fat. While the origin of the lesion appeared distinctly around the central veins, the distribution, like that of stasis, was irregular, and in streaky fashion ran from one lobule into another. At the periphery of these necroses, which terminated apparently more or less abruptly, were usually fairly well preserved liver cells, although these also showed edematous swelling, and in places beginning vacuolization of their protoplasm. Between them were dilated blood and bile capillaries, and the inter- and intracellular bile capillaries filled with bile were occasionally prominent. Of particular interest was the fact that the process of necrosis was not that usually observed in inflammatory destruction of liver tissue with the formation and coagulation of dead protoplasmic masses but appeared to be simple solution of liver cells, associated with vacuolization and central fat infiltration, leading to marked swelling of these cells. The faint nucleus, cell membrane, and the reticulum were retained well towards the last. The nucleus also showed only evidences of fading, chromatolysis. Fibrin could not be demonstrated in these sections. Clinically and anatomically this case differed from the results of uncomplicated stasis. Clinically it could be well differentiated by the progressing, deep jaundice, and anatomically by its cytolytic and fatty cestral necrosis and jaundice, leading to destruction of the architecture of the involved parts and setting free of blood and bile pigment. Peripherally, dilated blood and capillary vessels, bile stasis and edematous swelling and beginning occasional vacuolization of the cells were present. Entirely absent were evidences of an inflammatory character, any involvement of the larger bile ducts, or portal changes. The relation of this change to the chronic severe cyanosis and its immediate cause was still a matter for discussion. Originally he had stated that he was not inclined to think that the stasis and the necrosis with jaundice stood in direct genetic relation, but he believed that the lesion was due to a toxic invasion resulting in cytolysis. Continued studies, however, had associated the lesion so definitely with cases of advanced venous congestion and followed so definitely in its course, that he rather tended towards the view that a relation to it must exist. Two possibilities must be taken into consideration. One was that the lesion represented an additional infection from outside. Investigations for bacteria in these sections had not disclosed any support for this view. Further, the absence of any inflammatory reaction on the part of the liver might also be argued against it. On the other hand, it might be assumed, and he tended towards this view, that during the process of cell atrophy and stasis, the formation of cytolitic ferments might occur, inaugurating the terminating lesion. The passive features of the process, which were so characteristic, might be cited in support of this view.

An Unusual Form of Leukemia.—Dr. Lindsay S. Milne reported this case occurring in a well-developed, robust man, twenty-three years of age, Greek, who had come under observation in the City Hospital for the early secondary stage of syphilis, eighteen months before the date of his death. His inguinal glands at this time were slightly swollen, but his spleen and liver were not apparently enlarged. His urine showed no special change. He had suffered from gonorrhea five months previous to his coming to the hospital, but had no special illnesses before this. He remained five weeks in the hospital, being extensively treated with mercury injections. He continued these injections at his home for six months, and took internal mercury treatment for four months after this. He reentered the City Hospital in Dr. Camac's service, six months before his death, complaining of swelling of the glands of his neck which had lately commenced. He also had an enlargement of the axillary and inguinal glands, of rather more recent origin. His blood gave a positive Wassermann reaction and he was very weak and anemic. The spleen was found to be four finger-breadths below the left costal margin, and on the right side the liver extended three finger-breadths below. His blood count at this time showed: Red blood corpuscles, 3,400,000; hemoglobin, 55 per cent.; leucocytes, 52,000; polymorphonuclear, 10.5 per cent.; transitionals, 3.4 per cent.; myelocytes, 5.6 per cent.; eosinophiles, 1 per cent.; eosinophile myelocytes, 1.3 per cent.; small lymphocytes, 11.2 per cent.; medium sized lymphocytes, 30.7 per cent.; large lymphocytes, 12.5 per cent.; transitional lymphocytes, 6.8 per cent.; large mononuclears, clear cytoplasm, vesicular nucleus, 8 per cent.; medium sized, finely basophile granular mononuclears, 1 per cent.; large sized, finely basophile granular mononuclears, 2.9 per cent.; mast cells, 0.7 per cent; normoblasts, 4.1 per cent.; megaloblasts, 0.3 per cent. His weakness increased rapidly. The cervical glands, as well as those in all the lymphoid situations throughout the body, became rapidly larger, and breathing through his nose became progressively more difficult. He developed effusions, which had frequently to be removed, from his left pleural cavity, and occasionally also from the right. The spleen increased considerably in size and his anemia became much more noticeable. The leucocytes in his blood varied from 30,000 to 73,000, a rather larger number being present just before death. The relative proportions remained about the same, the eosinophiles and the neutrophile myelocytes, became slightly increased, the neutrophile polymorphs slightly reduced, while the large finely basophile mononuclears rose finally to 8.9 per cent. The number of normoblasts remained proportionately about the same, but the megaloblasts had increased to 2.7 per cent., on the day of his death. The red blood corpuscles had become progressively reduced, as also the hemoglobin; the color index however being always under one. His temperature had a slightly daily variation, as an average rising in the evening to between 99.5° and 100°, but sometimes reaching 100.8° as a maximum and 97.6° as a minimum. Various medications, including arsenic, mercury, and iron were used with no apparent improvement. At autopsy, the lymph glands all over the body were found greatly enlarged, firm, elastic, more or less discrete, and of a pink color, although some were dark purple from hemorrhage. In the axillæ and groins some of these had attained the size of a hen's egg. Microscopically, these were shown to be enlarged not only by infiltration of cells from the blood, but also by an active proliferation locally. On opening the thorax several large lymph glands were seen in the anterior inner part of the right vault of the diaphragm. One large hemorrhagic gland was situated

at the inner anterior part of the left vault close to the attachment of the pericardium. The outline of the pericardium was regular and its outer surface smooth. On section it was found to be enormously thickened. Posteriorly, it measured 5 mm. in the middle, and 1 cm. in the upper part. The lower portion and the region of the apex were only very moderately thickened. Anteriorly, however between the levels corresponding to the fourth rib and the upper border of the manubrium sterni, there was a very special thickening, about 4 cm. in diameter. This was in direct continuity with the pericardium and below the level of the fourth rib gradually became thinner, towards the apex being only about 3 mm. in thickness. This extensive pericardial thickening was very firm, apparently fibrous and of a pale yellow pink color. In its upper part it included several small lymph glands, some of which were hemorrhagic. The bronchial glands were considerably enlarged some of them also being dark red from hemorrhage. Microscopically, this condition in the upper part of the pericardium was found to be composed for the most part of fairly dense fibrous tissue, including very frequent rather ill-defined lymphoid foci which resembled closely the structure of hyperplastic infiltrated lymph glands in other situations. The appearances observed in this mass did not correspond to a tumor growth, but seemed to be the result of hyperplasia of the anterior mediastinal glands and most probably also of the thymus, although no Hassall's corpuscles were found. This was associated with extensive chronic inflammatory matting, and leukemic infiltration also to some extent had assisted in the process. There were not in the glands throughout the body nor in the pericardial thickening any evidences of tubercle, nor indeed were there any signs which made syphilis in any way a certain factor. No spirochetes were found in any situations throughout the body. The left pleural cavity contained a large amount of blood stained fluid. The pleura showed a chronic thickening due, as seen microscopically, to leukemic infiltration and chronic inflammation. The heart was dilated and flabby. The spleen weighed 900 gms. and was 21 cm. long by 14 cm. wide. It was of a dark reddish color and moderately firm. The Malpighian bodies were markedly enlarged, appearing as white spots through the section. Microscopically, the perivascular spaces were considerably distended by accumulation of cells. The sinuses also were frequently almost filled with, for the most part small, mononucleated cells. All the types seen in the blood were to be observed in these sinuses. There seemed, however, to be a very considerable proliferation of the lining endothelium. In some of the cells of this proliferation there were apparently distinct evidences of new formation of nucleated red blood cells. Some of the endothelial cells also seemed to be the seat of a deposit of coarse eosinophile granules, at first, apparently deposited around or on one side of the nucleus. These coarsely granular cells often attained considerable size and they all possessed a homogeneous, small, darkly staining nucleus. Some of them could be observed in process of direct division, and some also could be observed in the perivascular tissues. They never, however, assumed quite the appearances of the eosinophile myelocytes, as observed in the peripheral blood. The liver was moderately enlarged, weighing 2,150 gms., and, microscopically, showed a considerable deposit of hemosiredin pigment in the liver cells, and in the portal spaces a considerable infiltration consisting mostly of lymphocyte like cells although the other types seen in the blood were also represented. Many of these cells were situated perivascularly, but the capillaries themselves frequently were crowded with nucleated cells. To some extent in the perivascular spaces, but more in the interior of the vessel, there could be observed a relatively large number of coarsely granular eosinophile cells, mostly small, frequently appearing attached to the vessel wall, and containing small round homogeneous darkly staining nuclei, and were similar to those observed in the spleen. The lining endothelium of the capillaries, in isolated places in the interior of the lobules, also showed considerable proliferation, some of this apparently assisting in the production of leucocyte types, such as were seen in the blood and, to a small extent, the formation of nucleated red blood corpuscles could be determined. The kidneys were extremely enlarged, the left weighing 700 gms., the right 750 gms. and were for the most part pale, but very numerous hemorrhages were scattered chiefly through the cortex. Microscopically the enlargement was due, besides the hemorrhages, to a very extensive leukemic infiltration. In the perivascular spaces, besides a large number of small mononucleated cells, small clumps of relatively large cells having some of the appearances and giving the reaction of plasma cells, could frequently be observed. These cells generally contained numerous fine granules and some of them could also be seen isolated in the kidney capillaries. They did not quite resemble any type found in the peripheral blood. The intestines showed no specially abundant aggregations of lymphoid tissue. The bone marrow was unusual for any case of leukemia, being dark red in color and almost wholly erythroblastic. There was a relatively small infiltration of leucocytes from the blood, but only a very slight formation of polymorphs, myelocytes, lymphocytes, and eosinophiles. The reason for this almost exclusively erythroblastic marrow might have been that the destruction and loss of red blood cells was specially severe, and that the bone marrow, the usual site of new blood formation, became, of necessity, practically entirely devoted to its production, assisted to a small extent, as has been mentioned, by the spleen and liver. A great proportion of the leucocyte types found in the blood were evidently derived from some other sources than the bone marrow. The greater part of the lymphocyte like cells, for instance, were evidently derived from proliferative processes in the lymphatic glands and from endothelial surfaces in the other tissues. In connection with the consideration of the development of the neutrophile and eosinophile myelocytes in the blood, it may again be noted that numerous coarsely granular eosinophile cells were found in apparently all stages of formation in the spleen, to a less extent in the liver, and occasionally in the lymphatic glands. Also, in the kidneys, were found clumps of large very finely acidophile granular cells which, of course, may have been formed by local proliferation from some of the cells which penetrated from the blood and locally developed, but also presented evidences that some of them got into the blood subsequently. These may then have been responsible for the production of some of the myelocyte cells observed in the peripheral blood. Occasionally also in the peripheral blood the myelocytes of both types could be observed in process of division. There seemed to be, then, in this case, some evidence which would lead to support Maximow's idea that myeloid tissue may be formed from any endothelial surface in the body, and not only from the bone marrow. This case, in conclusion, presented several interesting features, in being of a more or less mixed type of leukemia for some considerable time. Anemia, although usual in leukemia, was in this case particularly prominent and was associated with a very special degree of regeneration of red blood cells. One might almost place it in the category described by v. Leube as "leukenemia," where leukemia of either variety is associated with anemia of the pernicious type. Sternberg has designated a type, which in some ways resemble this case, as "leucosarcomatosis" or an associated lymphosarcoma with leukemia. The present case, however, differed from the type described by Sternberg, in the blood picture and in there being no definite evidences of tumor growth in

the anterior mediastinum, lymphatic glands, or elsewhere. The condition appeared to be due to some chronic toxic process associated with marked blood destruction and extensive reactive changes in the tissues, particularly of the lymphatic glands, spleen, liver, etc. It is known that various intercurrent diseases can, to some extent, modify the appearance of the blood in leukemia and in this relation the question arises as to whether syphilis was merely a coincident process, a modifying condition, or even the essential etiological factor in the disease.

Report of Standing Committee and Other Observers Regarding the Symptom Complex as Communicated by Dr. N. E. Brill at the January Meeting.—Dr. C. N. B. Camac reported that he had a letter from Dr. David Bovaird stating that he had had a case showing the symptom complex as set forth by Dr. Brill and he called on Dr. Elsberg of Mt. Sinai Hospital who gave the history of a case of acute infectious fever of unknown origin. Dr. Camac stated that a meeting for the discussion of this subject had been planned for next December when physicians from Boston, Philadelphia, and Baltimore who had been studying cases of this nature would be present. In the mean time he hoped that physicians would be on the lookout for cases of this kind and would report them.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of September 24, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	662	156
Diphtheria	188	19
Measles	51	6
Scarlet Fever	82	4
Smallpox	—	—
Varicella	9	—
Typhoid Fever	133	11
Whooping Cough	50	5
Cerebrospinal Meningitis	6	2
Malarial Fever	—	—
Totals	1,181	203

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended September 23, 1910:

CHOLERA.

THE CARBOHYDRATE DIATHESIS.

By W. E. DEEKS, M.D.,
CANAL ZONE,
CHIEF OF MEDICAL CLINIC, ANCON HOSPITAL.

In June and July, 1904, the author published a paper in the *New York Medical Journal* entitled "The Carbohydrates as Ætiological Factors in Stomach Disorders," in which he endeavored to show that most of the socalled idiopathic indigestions or dyspepsias were due to dietetic errors, particularly the ingestion of sugars and starches in excess. Necessarily this does not include indigestions arising from other causes. In other words, if no constitutional or organic disease or dyscrasia; no local inflammation such as appendicitis or cholecystitis; and no functional disorder as hysteria or neurasthenia exists—all of which give rise to digestive disturbances, and the individual suffers from indigestion—then sweet and starchy foods in quantity or in kind are responsible. They give rise to local disturbances by the inability of the stomach to handle them and more remotely through their fermentation; and resulting products are responsible for a large number of pathological conditions commonly referred to as due to errors in metabolism.

About one year after the above-mentioned publication, the author published another paper in the same journal treating of one group of these remote effects, in which he stated that he believed that all true rheumatisms were the result of an autointoxication from carbohydrate fermentation when this group of foodstuffs was taken in excess and not properly assimilated. The object of this paper is to extend the clinical observations resulting from the remote effects of carbohydrate ingestion, and at the same time to confirm and accentuate the opinions expressed in the aforesaid publications.

The sources from which medical facts crystalize are numerous. One of the most important is clinical observation. In recent years this appears to have played a subsidiary rôle when viewed in the light of the dazzling discoveries in pathology, bacteriology, physiology and physicochemistry. At present, unless one can demonstrate a clinical observation by a mathematical calculation, or make it subserve Koch's laws, it will probably be received with incredulity by the profession at large. Clinicians, however, believe that many physiological functions are peculiar to vital cell protoplasm and cannot be elucidated through the agency of the microscope or test-tube experiments. As clinical observation was the first method by which a true understanding of morbid conditions was obtained, so it stands to-day an important factor with the aid of modern methods of research in the interpretation of morbid phenomena. The subject must be treated clinically in this paper, and the conclusions drawn are based upon evidence accumulated in the observations of years under specially favorable conditions.

The observations upon which this article is based began in Montreal, were continued in New York, and during the last three and a half years in the tropics. The opportunities to confirm and extend them have been so numerous and convincing that the writer feels that the presentation of them is now due the profession. Before discussing the observations made, I wish to predicate a few important physiological facts bearing directly on the subject. (a) Man belongs to that great group of animal life classified by Bergmann as homoiothermic, because they maintain a more or less constant temperature, irrespective of the environment. (b) In order to maintain that temperature, water, oxygen and a certain amount of organized food material is necessary. (c) Through the medium of cell metabolism, physiological changes are brought about in them by which the cells are nourished, waste products eliminated and heat generated; the whole process regulated by a more or less automatic nervous mechanism. (d) As more heat is dissipated in cold climates than in warm, necessarily food with less energy-producing units or calories is required in the latter than in the former. If the same dietary be maintained, undoubtedly a greater amount of work is thrown on the heat-regulating mechanism and the eliminating organs in the summer, resulting in irritation, if not pathological changes. (e) Exercise also plays an important rôle. Landois states that per kilogram of body weight a man at complete rest requires from 32,000 to 38,000 calories; at light work, requires from 35,000 to 45,000 calories and at hard work requires from 50,000 to 70,000 calories. (f) According to Liebig (taken from Landois), "foodstuffs subserve two purposes, namely, as plastic for the growth of the body, and, as respiratory, for the generation of heat. The former includes especially the albuminates, the latter especially the non-nitrogenous carbohydrates and fats." (g) Landois also states that 80 grammes (2¾ ounces) of proteid is absolutely necessary for the proper nutrition daily of a man weighing 154 pounds, and from three and a half to four and a half times as much carbohydrates and hydrocarbons. (h) If food stuffs are not taken in approximately the proper proportions, necessarily the excess must be eliminated and the human organism is called upon to do this not only by its own vital mechanism, but through the aid of bacteria which plays such an important rôle in physiological processes. Redundant or effete matter nature takes care of either within or without the body through bacterial fermentation and oxidation processes.

With these physiological premises in view, in combination with clinical observations, are based the conclusions which follow. The carbohydrates in excess are subject to fermentation, chiefly in the

stomach, but also in the intestines. There are two distinct forms of carbohydrate food which require discussion separately, as they give rise to a different symptomatology, namely, sugars and starches. The sugar eater has usually a very red, irritable tongue, rapidly recurring hunger, with a ravenous appetite quickly and easily satisfied, red fauces, a tendency to heartburn and ineffectual belching. Children are anemic, badly nourished, pasty looking, irritable, restless, particularly at night, suffer frequently from enuresis; they have decaying teeth, are constipated, at times alternating with diarrhea; are subject to rheumatism, chorea, iritis, recurring bronchitis and sore throat. In early infancy they are always prone to gastrointestinal disturbances and are the victims of eczema on the head and face.

The starch eaters are those who partake freely of bread, toast, potatoes, yucca, yams, etc. They are prone to take on flesh, are anemic, have flabby, tooth-indented, coated tongues, bad breath, chronic pharyngitis, and chronic cough, have little desire to eat, but when the first food is taken in the stomach, the appetite is stimulated and they eat enormously. One or two hours after eating they have left hypochondrial distress, belch large quantities of gas, have cardiac asthma, are constipated. They suffer from rheumatism, acute or chronic, lassitude, mental lethargy and drowsiness. The women are the subjects of dysmenorrhea and all forms of catarrh. Children handle starchy foods better than adults, but tend to become potbellied and anemic. I have pictured here the two extremes and they merge gradually into each other, depending upon the nature and quantity of the two classes of food ingested.

It does not lie within the scope of this paper to detail further the reason why this fermentation takes place. That has already been done in a former paper. I wish, however, to lay particular stress on the symptomatology of the conditions referred to, both local and remote. During three and a half years' residence in the tropics I have had unusual opportunities of studying the effects of diet in people of all ages, races and classes, and from the observations made and the results obtained, feel convinced that the carbohydrate diet in the tropics and in all warm climates is responsible for a very large percentage of the suffering of the human race. Although this country is prolific in a great variety of fruits, the Panamanians seldom use them as articles of food, except in the form of sweet drinks. Green vegetables are equally sparingly used. Their food consists chiefly of meats, fish and poultry, rice, potatoes, yams, yuccas and sweets in all forms and great profusion. In other words, a meat and starch and sweet diet practically devoid of fruit and green stuff. Until recently the Canal Zone population has been compelled to adopt a similar diet. The supply of green vegetables and fruits has been inadequate. In lieu thereof, canned goods, bread, rice, potatoes (Irish and sweet), syrups, artificial honey and rich jams are consumed in great quantity. The results of such a diet are seen so frequently and yield so promptly to treatment that there appears to be no doubt as to their etiological importance.

Climatic conditions here throughout the year are similar to the northern summers in temperature, but, owing to the great humidity, are conducive to more inertia, consequently less physical exercise. If then, because of the high temperatures, because of the inertia, a heat producing, energizing diet is taken, can we expect otherwise than a fermentative process with clogging of the emunctory organs in their efforts to eliminate what should not be taken? It is certainly surprising and satisfying to both physician and patient to observe the results when the sweet and starchy foods are substituted by fresh fruits and green vegetables and the starches thus reduced to a minimum. Some will states that they cannot tolerate fresh fruits, that they "sour on their stomachs." That is invariably true when patients are suffering from the acid stomach of a sugar indigestion, but when the diet and acidity are corrected, fresh fruits are tolerated in almost any form, and the natural sugars in them do not suffer the fermentative change.

As stated in a previous article, sugars in the stomach are prone to become oxidized in some of the organic acid series, which are locally irritating, and being very diffusible, are readily absorbed. The starches, though giving locally a different symptomatology because of their bulk and the difficulty of acidulating the mass, permitting CO_2, fermentation and flatulence, utlimately in part result in sugar and intermediate products and are prone to the same processes. Practically, then, almost all forms of stomach disorders can be referred directly to the action of these foods alone or in combination. The chronic pharyngitis so common north is more so here and results from the regurgitation of the gas and acid stomach contents. Here also is the secret of the early decay of the teeth and the stomatitis so comonly met with. Constipation is also a direct result of this dietetic diathesis with sporadic diarrheas, the latter particularly in children. Constipation is invariably associated with, if not responsible for, the anemias so common in all countries. When anemia supervenes with its consequent relaxed mucous membranes and atonic blood vessels, we have the potent factors in all catarrhal conditions, nasal, bronchial and vaginal. This combination of anemia and gastric hyperacidity due to sugar fermentation, I believe, also leads directly to gastric and duodenal ulcer. Even appendicitis has its history of constipation always, and the frequency of its occurrence among our patients certainly suggests the same cause. Whether the carbohydrate diet be directly responsible for the above-named conditions or not, one thing is certain, that when it is replaced by a fruit-vegetable diet, chronic constipation, indigestions and anemias, whether of short or long standing duration, disappear and the patients recover. Clinical evidence is abundant in confirmation of this statement.

We now come to a consideration of the effects of the absorbed products of carbohydrate fermentation when circulating in the system. In a former paper the writer stated his belief that all true rheumatisms and rheumatic phenomena were caused by the irritating products of gastrointestinal fermentation, chieflly carbohydrate acting on fibrous connective tissue on which it is selective. Fibrous connective tissue is the supportive tissue of all cell units in the organism, and in consequence, every part of the body is susceptible to the action of the rheumatic poison, the localization of which is determined by physiological congestion or injury (I say true rheumatisms in contradistinction to the socalled rheumatisms, or rheumatic pains occurring in such affections as chronic nephritis, syphilis, locomotor ataxia, pachymeningitis, herpes zoster, compression myelitis, etc., etc. In the carbohydrate group of rheumatic phenomena we have a great many different manifestations because of localization, but all due to the same or related toxic substances. I will chiefly

enumerate them: endocarditis, pleurisy, arthritis, tonsilitis, neuritis, iritis, corneal ulcers and chorea. When the connective tissue in the muscles is involved, we have muscular rheumatism, and when the modified connective tissue, cartilage, is involved, we have rheumatoid arthritis. Two other forms of rheumatism I wish now to mention hitherto not considered in this group. They are sufficiently important to be considered in separate articles. I refer to dysmenorrhea and enuresis. These two conditions to me were therapeutic problems I always hated to face. I never suspicioned their etiology and only guessed at the means of relief.

In carrying out the methods of diet here advocated, Dr. A. B. Herrick, in charge of the gynecological clinic, suggested the probable relationship of dysmenorrhea to the carbohydrate diathesis, as certain patients had been relieved of this trouble when dieted for other conditions. Since he drew my attention to this, I have investigated a great many cases and am in a position to confirm it in the great majority. I do not say in all. In other words, most dysmenorrheas are rheumatic due to the action of the poison in the connective tissues of the womb, and yield promptly to a rheumatic treatment of diet and salicylates. Recently a young lady under my observation was at a loss to understand why she had a painless period toward the end of Lent, which she kept by cutting out all sweets, and that is but one among many examples. Enuresis is but a rheumatic affection of the bladder and yields promptly to the same treatment. From an extensive experience in connection with the above-mentioned rheumatic phenomena, the writer is in a position, not only to affirm what he years ago contended in regard to the relationship of rheumatism and a carbohydrate diet, but to extend the scope of that relationship.

We now come to a consideration of the effects of the fermentative products on the eliminative organs. First on the alimentary tract. I have already referred to the sporadic diarrheas which occur and to the habitual constipation which is so general and its secondary effects. The worst effects, however, are seen in the enterocolitis of marasmatic infants fed on condensed milk, between 60 and 75 per cent. of which is sugar in some form. It is certainly striking what rapid changes are wrought when the infants are fed on a proper combination of this and the almost sugarless concentrated milks of commerce, diluted with water or barley water. On the kidneys also, which are called upon to eliminate so many products, the result of autointoxication, there seems to be a relationship between a carbohydrate diet and some of the insidious forms of nephritis commonly referred to as idiopathic. On the skin there is absolutely no doubt. Two great classes of skin affections are directly caused by a carbohydrate diet due either to the poison while circulating in the blood, or during its elimination by the skin. I refer to eczema and acne in all forms, acute and chronic. The manner in which they clear up on a carbohydrate free diet is one of the most striking things one sees in medicine. I have seen weeping eczemas in young people cease exuding in twenty-four hours and absolutely dry up and disappear in a week. The more chronic forms yield more slowly and usually require some digestive correctives as well, because of their chronicity. It is a frequent observation to see an acne eruption follow a sweet and pastry debauch, and I have had as brilliant results in this form of skin affection as in the eczemas.

One other group of conditions I wish now to discuss, the importance of which is such that mention should be made of it, though my observations have not been as extensive as I should like. Of the causal relationship there can be no question. I refer to the effects of a carbohydrate diet on the respiratory tract. That a relationship between recurring bronchitis and the sweet diet of childen exists, there is no doubt. I have had too many cases in direct proof. When, however, we consider that all constitutional conditions which produce a lowered vitality and a bronchial catarrh form a suitable nidus for the development of the tubercle bacillus, then the importance of diet becomes a serious problem, not only in the prophylaxis, but also in the treatment of this grave affection. We know and see here many cases of tuberculosis apparently provoked by an attack of neglected influenza which produces the conditions above named, and when we know that a carbohydrate diet tends to bring about a similar constitutional condition, and when we see here case after case of pulmonary tuberculosis, developing without hereditary factors or any other constitutional or exciting cause but that they have suffered for variable periods with indigestions, throat catarrhs, anemia, etc., and a carbohydrate diet history, then the relationship becomes more than casual.

I have seen here a child invalided from exceedingly severe recurring attacks of pharyngitis, tracheitis and bronchitis to such an extent (climate being presumably the exciting factor) that peremptory orders by physicians of repute had been issued for a northern sojourn, clear up absolutely in two weeks' treatment. In three months the child gained twenty-five pounds, and to my certain knowledge, has not had a sick day in two years. She is now eleven years of age. So many examples of similar conditions have come under my observation that where doubt existed a few years ago as to the etiology, now positive assertions can be made. I have spoken briefly in reference to a series of conditions and their etiology so apparently different in their manifestations that most physicians will, I fear, think that all bounds of credulity have been passed.

In support of the position I take that dieteic errors are responsible for a tremendous amount of human suffering, I desire to bring to my aid some of the principles of biology and evolution. It is a well-known fact that a fresh-water hydra can be divided in sections and each division develop into a perfect animal. It is a rudimentary organism with little cell differentiation. The higher the development of the organism, the more cell differentiation and cell specialization for physiological functions. The lobster can regenerate a discarded claw, or the lizard a severed tail, but they cannot regenerate as do the hydra. They are more specialized.

When we speak of man we get the highest type of cell differentiation and specialization, the process of countless years of development and subject to only the slowest degree of modification. In him generations are necessary to structural changes anatomatically and physiologically. We know of none that the microscope can detect in historical times more than can be seen through effects of climatic adaptation, and these are transitory, not permanent. You may, with care, train a carnivorous bird to adopt a graminivorous diet and vice versa, and with it there will be profound changes in the digestive organs. But a bird being much lower in the animal scale than man is more readily subject to modification by changed environment.

No scientific man believes to-day but what his evolution was through many ages, antedating probably by thousands of years the historical period. From what we have been able to glean from the footprints of his development, until quite recently, he lived under the most primitive conditions when meat, milk, fish, fowl, fruit, vegetables and cereals could be his only diet. No pastry cook lived in those days to leaven, dextrinize and modify his cereals; he ate them plain, or at most, cooked. Sugar was unknown, except as he chewed the sugarcane, a local product, or tapped the sugar maple, also a local product, or sought the honey of wild bees. In fruits chiefly, in a natural form alone, could he indulge. In other words, sweets was not a natural food and is not now a natural food for the morphologically related animal kind. Not then being a natural food, he developed nothing to take care of it in his stomach.

It is a well-known fact that in the human stomach sweets undergo no digestive change. There is no ferment, organized or unorganized, to digest cane sugar, and what is not of use is deleterious. If taken in solution on an empty stomach, sugars pass directly on into the intestine and there meet a ferment which converts them into assimilable products, but when mixed with food, they are retained until the whole mass is acidulated, and before they can pass into the intestine they are converted into the products so deleterious to all tissues. If we but reflect for a moment, we see that sweets and starchy foods form the greatest factors in our diet. The Irish potato, practically all starch, is a product of the 16th century, and to-day is ubiquitous in our dietary at least two meals a day. Bread is used in every meal, a fermented, partially dextrinized product, chiefly starch, but still containing some nitrogenous food.

Sugar forms a part of the meal in some form three times daily. It is a solid alcohol artificially extracted from cultivated plants, tubers, and the wild sugar maple similar in chemical composition to the starchy foods, more prone than they to fermentation, and more irritating products result. In the attractive manner sugars are now manufactured and sold in the form of sweets and candies to stimulate their consumption they have crept into every man's home. They have outrun in the amount of their use the physiological evolution of man and have become, I firmly believe, the greatest curse in modern civilization. I do not except alcohol in all its varied forms, and believe that a popular movement against their present method of use would do more to lessen human suffering than the temperance movement against alcohol. One often hears the statement that the suffering and pain so common in the higher walks of life are a concomitant result of the evolution of modern civilization. If so, modern civilization must be largely gastronomic, subject to rapid evolution and involution depending largely on diet.

Natural fruit juice is antiseptic and will not disagree if one is not a sugar eater. One has to examine the recent magazine articles on digestive fads of all kinds, to see the reason of their successes. A great many have hit upon the practical demonstration of the principles, herein taught, blindly. Some of them are the Salisbury treatment, Fletcherism, fasting, milk diets, physical culture, dietetic sanatoria, alkaline springs, etc., ad infinitum. They all mean a cutting out of sweets, an alkalinization of their fermentative products in the stomach, or an increase of exercise and massage to a degree to increase oxidation. One can handle much more of the carbohydrates in cold weather and during exercise than in warm weather and when living a sedentary life. That is why we have more indigestion, rheumatism, etc., among women than men, and among the sedentary living than the physically active. It is often difficult to get a true dietetic history. Patients attempt to conceal the use of sugar as they would shun an inquisition on alcoholism. One must take up each meal in order and endeavor to find the exact quantity used in the food and in drinks of all sorts; also the amount of candy consumed, ice creams and malted milks. It is surprising often to find what people consume in an ordinary diet. The candy shops with wide open doors to children of all ages where their gift pennies are spent are a veritable curse in the land, poisoning the youth of the country and undermining their physical and mental development. Can we find a more pitiable picture of their effects than in the emaciated, anemic, constipated child, with coated tongue, decaying teeth, fickle appetite, sporadically fed at all hours, fretful, irritable, sleepless, suffering from enuresis, rheumatism, chorea, frequently developing heart disease, dwarfed in its physical and mental development? This is the every-day picture of a sweet-eating child; or of a young girl suffering from one or more of the above, merging into womanhood, the victim of dysmenorrhea, resorting to sedatives and ill advised by members of our profession, subjecting herself to curettage, ovariotomy, etc., and finally deprived of that which makes for true womanliness, becoming a physical and neurasthenic wreck, the prey of all quacks and patent medicine venders. These pictures are not overdrawn. They are every-day occurrences in a clinical practice. They can be seen in numbers in every outdoor hospital clinic every year. Of such are our sanatoria filled, and we physicians too often say modern civilization, uric acid, and nervous prostration.

From my experience the following can be truthfully predicted: Granted a child is born perfectly healthy and free from constitutional taint, if properly fed and living in a good hygienic environment, he or she will suffer no illnesses, except those due to the infectious diseases, and then the resistance will be such that no fear need be entertained of the favorable outcome. The principles above advocated are those in vogue here and to their more or less general adoption, I attribute the low sick rate and exceedingly low infant mortality among those living in the Canal Zone under the care of our staff. One has but to read in our medical publications of the appalling death rate in most tropical countries to appreciate the results here obtained by this method of procedure. Enterocolitis, so fatal in warm climates, we rarely see in a white child, and then only as a result of parental carelessness. Among the poor, when canned condensed milk and patent foods are used, we find all our badly nourished, marasmic children with their enterocolitis, etc. Some of these are so advanced when we first see them that all treatment is futile. It is astonishing, however, from what profoundly morbid conditions they recover when properly dieted.

In conclusion I wish to summarize that patients suffering from one or more of the following affections are consumers of an excess of carbohydrate food: Indigestion, gastric ulcer, decaying teeth, stomatitis, constipation, chronic pharyngitis, true rheumatic phenomena in all forms, eczema, acne, recurring bronchitis, anemia, most dysmenorrheas,

enuresis, etc. I believe the diet to be indirectly responsible for appendicitis, and frequently tuberculosis. Physicians may think that the position I take is extreme, but I am forced to these conclusions by my clinical observations and all that I ask is investigation before condemnation. I am not stating what the exact nature of the products of carbohydrate fermentation is; that belongs to physiological chemistry; but I do contend that every statement above made can be abundantly verified clinically, and from a humanitarian standpoint, the results obtained are worthy of further investigation. In the tropics, unless engaged in active physical exercise, the nearer we keep to a diet consisting of meat, fish, poultry, milk, green vegetables, and fruit, the less suffering we have. In this combination we find an energizing, tissue forming, low heat-producing food, free from fermentative properties and containing enough of the indigestible vegetable cellulose to stimulate intestinal peristalsis and elimination. Sugars should not be consumed at all except in solution on an empty stomach, and then sparingly. The amount of starch ingested should be proportionate to the physical exertion involved.

RESULTS IN THE TREATMENT OF DIABETES MELLITUS.

By T. STUART HART, M.D.,

NEW YORK.

ASSOCIATE IN MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, VISITING PHYSICIAN TO SETON HOSPITAL.

In considering the results which we may obtain in the treatment of diabetes mellitus, we should apply the standards which we employ in other chronic diseases.

When we are called in to see a patient with an old endocarditis, with damaged valves and broken compensation, a pulsating liver, edema, and ascites, we do not expect to cure him. We know that we cannot smooth out the crumpled and deformed valves, we know that we cannot even restore the muscle wall to the state which existed before his attack of rheumatic fever. If we are fortunate and skilful, we can, however, get rid of his edema, relieve his cough and dyspnea, and get him into condition so that he may be able to walk about on the level and, with certain limitations, enjoy life. We know only too well that sooner or later the patched-up heart will again give out, but this merely tempers our satisfaction in being able to relieve him, and does not keep us from attempting to restore his equilibrium.

The situation is very different if we are fortunate enough to get him under control early in the course of his disease: at this time it is much easier to restore the cardiac function and we can teach him to avoid the stress which for him is too great. He may even attain a considerable "margin of safety," and, under a proper regimé, may hope for life of many years—with limitations, it is true, but not necessarily useless or unhappy years.

The results which we can obtain in diabetes are closely comparable to those we reach in chronic valvular disease. Rarely do we cure a real diabetic. Personally, I should hesitate to say that I have ever seen one absolutely cured, for I have never seen a case which I was willing to designate a true diabetic, who did not have limitations which the normal man does not have. I have seen them go on for years under very slight restrictions, without a trace of sugar or acetone in the urine, without thirst or polyuria or loss of weight; in fact, without a symptom referable to diabetes—and yet these restrictions, small as they may have been, were necessary to maintain this condition of health. The cases which we get early and in which we can secure the cooperation of the patient are those for which we can usually accomplish much. The advanced cases, characterized by great carbohydrate intolerance, acidosis, and emaciation, are far more intractable, but even these we can usually arrest for a time; and though we are obliged to admit that eventually the course will be a downward progression, we can do much to reduce the hardships and avert the suffering. Boils and carbuncles, those tortures of the untreated diabetic, are almost unknown in those whose hyperglycemia is kept at a low level.

There are many important elements which make for the successful treatment of diabetes, but if I were asked to select the one factor which is fundamental and without which success is impossible, I should certainly place first of all *a systematic record*. This record should include not only the usual history of the case and frequent notes on the physical condition and subjective symptoms, but should also show in a tabulated form the details of the urinary findings, the weight, the diet, and the medication. For a number of years I have used such a record: it is a folding card, 13x6 inches; one side is used to record the usual facts of the history, symptoms, physical signs, etc.; the other side is especially ruled in columns and headed with the following titles: Date: Amount in 24 hours: Specific gravity: Albumin: Sugar: Polarization before and after fermentation: Acetone: Diacetic acid: Oxybutyric acid: Ammonia: Urea: Weight of patient: Diet (protein, fat, carbohydrate, calories): Medication. A single card of this size will afford ample space to record 20 distinct observations. This is not only a labor-saving device, but also will afford at a glance information in regard to the progress of the case, which makes one confident that he knows what is going on. The keeping of such a record has a direct effect on both the physician and the patient. The physician cannot watch such a record from week to week without being impressed by the value of attention to details; as his treatment improves the condition of his patients, his enthusiasm increases (to treat diabetes successfully, one must have a great deal of enthusiasm); but the enthusiasm which is of real value must be based not on guess work, but on facts recorded in black and white. To one who has followed cases in this way, the effect on the patient is equally obvious, his confidence is won, he sees the care and attention which is being devoted to him, and this in turn (usually) enlists his cooperation; and this is the only sure means that I know of whereby this cooperation can be secured.

The *technique* of the management of a case of diabetes is most important. The patient must be educated to carry out all the directions with exactness. This can be most quickly and satisfactorily attained by placing the patient in a properly-conducted sanatorium, where his food can be accurately selected and weighed, his exercise properly regulated, and the excreta carefully preserved. There are, however, obvious difficulties in persuading a patient who does not feel very ill to enter an institution; therefore, his education must usually be conducted amid less favorable surroundings. It is surprising how soon and how accurately patients will learn to observe the necessary details. In my experience it is usually easier to teach a patient what he

must do for himself than to teach a nurse, who has had no special training in the case of those suffering from metabolic disorders, what must be done for the patient. The illustrative cases which will be reported in the present paper are of subjects all living at home; purposely no institutional cases have been reported, in order to emphasize the fact that with the proper supervision, education, and cooperation of the patient, most satisfactory results may be secured outside of the sanatorium.

The diet must be written out by the physician in the form of a prescription; it must express explicitly not only the kind, but also the quantity of food which is to be taken at each meal. The patient must be put upon his honor not only to take no food other than that prescribed, but also to take the exact quantity (no more and no less) expressly stated for him in the prescription. The patient should weigh his food for the first few weeks until he has become familiar with the amounts represented by definite quantities of the various kinds of food. For this purpose I have found most useful and convenient a special food scale which I have had constructed for the purpose.* All drugs except those prescribed should be expressly forbidden.

Detailed directions should be given for the collection and delivery of the urine. Not merely a specimen of urine should be submitted, but the whole 24 hours' quantity should be sent to the laboratory *in toto*. The 24-hour period should begin with an empty bladder and conclude by emptying the bladder. The 24-hour period should be so selected that at its conclusion the urine may be forwarded to the laboratory for immediate examination.

Our first procedure for the diabetic is to determine his *tolerance for carbohydrates*. This is accomplished by prescribing for him a "standard diet" consisting of a considerable quantity of fat, a moderate amount of protein with a minimum of carbohydrate, and to this is added a definite amount of carbohydrate (the "accessory diet.").

The "standard diet" should be practically carbohydrate free and should furnish not less than 30 calories per kilo of body weight. Thus for a patient weighing 150 pounds the "standard diet" should furnish about 2,000 calories.

*Journal American Medical Association, Vol. liii., p. 457, 1909.

The "accessory diet" should consist of a known amount of starchy food. This may be wheat bread or potato or oatmeal, or other starch-containing food. After experimenting with various forms of starchy food for test purposes, I have come to depend almost entirely on the Huntley and Palmer "breakfast biscuit." These are quite uniform in weight (10 grams each) and have a very constant starch content of about 5 grams.† As a primary test ("accessory diet"), I usually employ 4 of these biscuit with each meal (*i. e.* in 24 hours, 12 biscuit = 120 grams = 60 grams starch). After such a test the patient's carbohydrate tolerance is represented by the formula: Standard diet + 60 grams starch — x grams sugar excreted (estimated as starch) = carbohydrate tolerance. If the amount of sugar excreted is less than the amount of sugar which could be manufactured from the starch of the accessory diet, we speak of the patient's having a *positive* carbohydrate tolerance of 60 — x grams starch. If sugar is excreted in an amount greater than can be accounted for by the starch of the accessory diet, we regard the patient as having a *negative* carbohydrate tolerance.

Having established the carbohydrate tolerance on a known diet of this kind, we have a test which may be applied at any subsequent period to determine how far our measures have improved the patient's power of utilizing carbohydrate food.

As a rule, any real improvement in a diabetic will be shown by an improvement in carbohydrate tolerance. In a severe case the patient may, in spite of our best efforts, always show a negative carbohydrate balance, but with improvement this negative balance almost invariably becomes smaller.

The main element in the production of increased carbohydrate tolerance is a restriction, for a time, of carbohydrate food. This improvement in the power of oxidation seems to depend on the rest afforded the tissues by diminishing the work thrown upon them. The reduction of the carbohydrate food of the diabetic has an effect on the tissues quite parallel to that of restricted muscular exertion on the overtaxed heart.

The improvement which may be secured is illustrated by the following cases, which represent a number of different types of diabetes mellitus.

†Based on numerous analyses made in my own laboratory.

J. D. CASE 1.

Case I.—J. D., 55 years old. Married. Engineer. Family and previous history unimportant. Was first seen in January, 1907. Sugar was discovered in his urine two years ago. He complained of passing considerable quantities of urine (was obliged to get up at night), thirst, furunculosis of scalp, and pains about the shoulders. Physical examination showed a stocky, well nourished man; height, 5 ft. 7 inches; weight, 184 pounds. Heart and lungs normal. Liver felt one inch below the margin of the ribs in the right midclavicular line. Abdomen otherwise normal. An abbreviated record is given in the table preceding. It is a typical record of a mild diabetic; it will be noted that during the early part of the record the limits of tolerance were not infrequently overstepped, but a return to the more restricted diet was soon followed by an increased tolerance. For something over a year, when last seen, he had been indulging in 100 grams of wheat bread and 150 grams of potato (or the equivalent of these) per day with no glycosuria. It is true that during this period of three years he has lost some 19 pounds in weight, but this I regard as an advantage rather than otherwise, as the normal weight for his height and age should be 158 pounds.

12.	1800	1012	+	0	0	110½	"	10	90	60	30	32	0	+32

Even after we have established a considerable carbohydrate tolerance, it will be found that an excessive amount of starchy food will result in glycosuria, and sooner or later in diminished carbohydrate tolerance; it is therefore admissible to allow a patient not more than 70 per cent. of the amount of carbohydrate food which it is found he can utilize without glycosuria. Directions should also be given to distribute this food equally in the three meals of the day, as by this means a considerably larger amount can be tolerated than when a larger quantity of starchy food is taken at one time.

Case II.—M. C., 48. Married. Piano manufacturer. There is no family history of diabetes. Father died of pneumonia. He is a moderate user of alcohol and tobacco. He had gonorrhea 30 years ago; denies syphilis. Always has been rather thin. Has never been seriously ill. For the past year he has had more or less "stomach trouble," characterized mainly by epigastric pain after eating.

He first came to me March 29, 1909, complaining of the presence of sugar in his urine, thirst, and polyuria. The preceding November he first noticed his thirst and polyuria. In December his urine was examined and sugar was found. He brought with him the following record:

The above record is characteristic of a type of diabetes more severe than Case I. When first observed he had a negative carbohydrate balance of 14, he was very much emaciated and nervous, and in addition to excreting a considerable amount of sugar, he exhibited a mild grade of acetonuria. As a result of three months' careful dietary regulations, he had converted his negative carbohydrate balance into a positive balance of 32 grams. His acetonuria had disappeared. He was feeling less nervous and more vigorous.

I should have felt much better satisfied if I could have observed him long enough to obtain an increase in weight, but when last seen no improvement in this direction had taken place. The administration of whiskey and olive oil was undertaken with the expectation (which I have frequently seen verified) that this addition to the caloric value of the restricted diet would result in an increase of weight, thus increasing his "margin of safety."

Case III.—I. L., 37 years of age, married, native of Finland; has been in U. S. 6 years. Carpenter. Family history good. Nine years ago, in India, he was in the hospital eight months with fever (up to 107½°) and chills; was told he had malaria at his time. Otherwise he has always been well and strong. He first came to me on March 20, 1908. In January, 1908, he had a short febrile attack, with general aches and pains. Immediately following this he began to pass large quantities of urine; he was obliged to urinate every hour. He was very thirsty and his mouth and throat were excessively dry. These symptoms have continued to the present time, and in addition he complains of some shortness of

breath and intermittent pains in his arms and legs. Sugar was discovered in his urine in January, 1908. In December, 1907, he weighed 195 pounds. When first seen he was excessively nervous, said he had not had a night's rest for a month on account of the polyuria. He feels weak, tires easily, and is, therefore, unable to work.

Physical Examination.—Height, 5 feet 6 inches; weight, 165 pounds. Good color, appears well nourished. Lungs normal. Heart not enlarged, rate 100, systolic murmur at the apex. Abdomen normal.

A study of this record presents some very interesting and instructive facts. When first seen, the patient was passing over 6 quarts of urine, containing about three-quarters of a pound of glucose, and a considerable amount of acetone and diacetic acid, in 24 hours. On the "standard diet," plus an accessory diet of 100 grams of wheat bread, on March 26, he showed a *negative* carbohydrate balance of 84 grains. On a diet gradually restricted by reducing the amount of bread allowed, the carbohydrate tolerance rapidly increased, so that in six weeks (May 4th) he stopped excreting sugar and for the first time showed a positive carbohydrate tolerance. By June 13 he was able to take 135 grams of bread without the excretion of glucose, and showed a *positive* carbohydrate balance of 81 grams. It is also interesting to note how his acidosis cleared up as his carbohydrate tolerance improved, and entirely disappeared on the day that he first showed a positive carbohydrate balance. The general improvement in the patient's condition was equally remarkable: Thirst and polyuria had disappeared, he was able to get a good night's rest, and hed entirely lost his nervousness and general aches and pains. He felt vigorous and energetic, and was able to perform his usual work without fatigue.

The patient was not seen until five months later, when, feeling not as well as usual, and somewhat easily tired, he came for advice. Until the middle of October he had kept strictly to the diet which had been prescribed in June, which consisted practically of the "standard diet," plus 100 grams of wheat bread, or its equivalent in potato. In October, on the advice of a friend, he began to eat freely of "Jireh bread," a much-advertised diabetic food. The result is readily seen in his tabulated record, which shows on November 11 an excretion of 115 grams of sugar. His diet was again restricted, and the glycosuria cleared up very quickly. After a short period he was allowed to return to small measured quantities of carbohydrate food, and on March 20, 1909, when last seen, he had a *positive*

carbohydrate balance of 102 grams when he was tested with an accessory diet of 120 grams of wheat bread and 100 grams of potato. He was working regularly, and reported that he felt "as well as he ever had in his life."

Case IV.—E. M. H. 33. Single. Native of U. S. Supervising engineer of some important iron mines in Cuba. Mother died of nephritis; there has been no diabetes in his family; his family history is in other respects good. He has never had a serious illness; has spent most of his time in the open air. He indulges in about eight cigars and one cocktail a day. His usual weight has been 122 pounds. In March, 1909, he was struck on the head by a rock, which resulted, as far as he knows, in only temporary bruises. In July he noticed he was passing large quantities of urine; this was examined, and a large amount of sugar was found. His diet was somewhat restricted in starches and sugar, and he came North for a rest. During the summer the polyuria continued, with great thirst and polyphagia. He was obliged to get up two or three times at night to urinate. He lost weight progressively and became nervous and irritable, and wearied on the least exertion. He came first for advice on October 1, 1909.

The physical examination showed the following facts: Height, 5 feet 8 inches; weight, 115 pounds. Very thin, nervous and weak. Heart and lungs normal. Abdomen normal, neither liver nor spleen were enlarged. Knee jerks present. Pulse 80, regular, good force and volume. Slight thickening of radial arteries.

The record of his subsequent progress is as follows:

The above table covers three periods. During the first and last periods he was in New York and under close observation; during the intermediate period, November 1, 1909, to March 16, 1910, he was under the care of his physician in Cuba, who communicated with me by letter.

This is a case which I regard as a severe and dangerous type of diabetes, and in spite of the very great improvement I cannot but feel anxious as to the ultimate outcome.

The points of especial interest here are: (1) The great polyuria and glycosuria which were reduced to a small volume and a low grade; (2) the conversion of a negative carbohydrate balance of 34 to a positive balance of an equal size; (3) a considerable increase in weight (much to be desired in cases of this type); (4) the considerable degree of acidosis represented by an output of over 3.5 grams of ammonia which was for a time symptomatically combated with soda and later disappeared coincidently with the improvement in the carbohydrate tolerance; and (5) a very remarkable change of a nervous, depressed, and listless man into one who was able to do and enjoy a large amount of hard work without very great fatigue.

It will be noted that the caloric value of the food in this case was enhanced by the addition of alcohol; in his strict diet a large amount of fat was prescribed, and it was deemed inadvisable, in view of the considerable acidosis, to prescribe additional fats like olive oil, etc., especially as he could not be under conditions to permit of the exact estimation of the degree of his acidosis.

It is to be observed that in several of the cases cited there appears a considerable glucose excretion even when the patient was on the "standard" or absolutely "strict" diet. A part of this (say 10 grams) may be accounted for by the small amounts of carbohydrate in the prescribed diet. The remainder undoubtedly had its origin in the protein of the food. It has been definitely established that under abnormal conditions the protein molecule may furnish from 50 to 60 per cent. of its weight of glucose. In such cases, therefore, we find it of great aid in improving carbohydrate tolerance to reduce the protein content of the food to 100 grams or even less for short periods. This was the course adopted for short periods in Cases III and IV.

Other means are at our disposal for improving the carbohydrate tolerance of the diabetic. Exercise for the robust and overweight. Rest for the weak and emaciated. Freedom from care and worry for all. Drugs such as codeine, atropine, and arsenic may be of aid, but as our mainstay we must depend upon diet adjusted to individual needs.

The above examples will serve to illustrate what we can do for our diabetics of both mild and severe types when taken in hand at a comparatively early stage, and when they are kept under proper supervision and control.

The lack of space deters me at present from a discussion of the very advanced cases. At times we are able to obtain a carbohydrate balance of only a few grams, or in still more advances cases we must be content to convert a large negative balance into a smaller one. In these the acidosis problem becomes a very prominent factor, and it is all-important to watch the quantitative progress of the formation of the acetone bodies and combat this with all the means at our command. Often we can obtain the same proportionate improvement as has already been indicated in the less advanced types, but the improvement is usually less enduring and less effective.

What I wish to emphasize is the importance of taking proper care of the mild type of diabetics, and of subjecting them to suitable restrictions *early* in the course of the disease. By the painstaking control of the diet, under the guidance of accurate records based on careful observation, the progress of diabetes, in the majority of instances, may be so checked that it will never reach the most severe form of the disease. In other instances, although they become more severe in spite of our best efforts, we are nevertheless able to materially hinder the progress of the malady, we may save our patients much suffering and lengthen their lives by a number of years.

130 West Fifty-ninth Street.

RECENT PROGRESS IN ANESTHESIA.*

By JAMES TAYLOE GWATHMEY, M.D.,

NEW YORK.

The term "recent progress,'" as applied to the science of anesthetics, is capable of different interpretations. If we accept the definition placed upon the term by the custom of the American Medical Association, in publishing through its journal papers read eight or twelve months previously, I may safely consider myself timely in presenting certain phases of progress in this important department of surgery. If by the term is meant some late and generally accepted discovery, then my paper will of necessity be limited in its scope. If, on the contrary, it conveys the idea of facts known and applied by a few but not generally accepted by the medical profession at large, it will be possible for me to discuss, in a general way, some very important truths concerning the administration of anesthetics.

There is a great and growing necessity for some kind of medical clearing-house, some society or body of men whose duty it shall be to investigate, accept, suitably modify, or reject each new discovery. Furthermore, research and experimentation by individual physicians should be encouraged and fostered. The laboratories of our great colleges should be open to them, and they should be assisted in their experimentation by trained laboratory workers. If these two ideas could be put into practical execution progress would be made by leaps and bounds, and the worker would see the results of his efforts immediately made available.

The basis of my work may be found in the theory of narcosis formulated by Prof. Hans Meyer, of the University of Vienna, which is as follows:

"The narcotizing substances enter into a loose physicochemical combination with the vitally important lipoids of the cell, perhaps with the lecithin, and in so doing change their relationship to the other cell constituents through which an inhibition of the entire cell chemism results, and the narcosis immediately disappears as soon as the loose reversible combination dependent on the solution tension breaks up. Further, substances chemically absolutely indifferent, as the volatile saturated hydrocarbons, can act as narcotics.'

This theory of narcosis in a measure explains my own work in the administration of anesthetics at different temperatures. In 1904 I experimented with oxygen to determine its value as compared with air. Small animals were used as subjects. In these experiments I used a closed mask with an expiratory valve, exactly the same amount of enesthetic being employed to start with in each case, the flow of air or oxygen being so regulated that the technic in each instance was the same. In order to determine the difference in toxicity of the combinations used, the time was taken from the application of the mask to the stoppage of the heart. The results were so conclusive that I stated positively that oxygen increases the value of all anesthetics as regards life, without decreasing their anesthetic effect.

Again, in 1906, I experimented with the different anesthetics, especially with chloroform, at 100° F. and at room temperature. I found it took just twice as long to kill with the warm anesthetic as with the cold. Warm chloroform and oxygen are safer than ether and air, although the safety of all anesthetics is proportionately increased by the addition of oxygen and by warming.

If my theory of the value of heat as regards the safety of anesthetics be true, then especially is it indicated to assist in more rapid recovery after the anesthetic, and to prevent nausea and vomiting. With this idea in view, for the past six months I have been applying hot towels to the patient's face as soon as the anesthetic is discontinued. The results have been most gratifying. In order to test this last procedure properly I anesthetized three animals for ten minutes, afterwards placing them in receptacles, one at 0° F., another at 100° F., the third being allowed as a control, to come out in the room temperature. In each instance the animal in the hot chamber made a slightly more rapid recovery than the others. The animal in the cold box came out with chills, while the one in the room temperature came out a close second to the one in the hot box. The animals were changed in position on three successive days, but the results were the same.

Electric Sleep: Electrical anesthesia has not been developed to a stage where it is practical for clinical use, but it may be employed in the laboratory instead of chloroform and ether. My purpose in experimenting with electrical anesthesia was to cut down the current to one-third and supplement this with enough morphine to carry on the anesthesia without any unpleasant symptoms. With the assistance of Drs. Adams and Cunningham at one time, and later with Dr. Rabinovitch, I experimented along these lines. One or two beautiful tracings were obtained, but we were convinced that this branch of medicine had not been developed sufficiently to justify a continuance of the work. Most

*Read before a combined meeting of the Suffolk District Medical Society and the Boston Medical Library, Boston, Mass., Dec. 1, 1909; also, before the Audubon Medical Society, New York City, May 6, 1910.

of us were fully convinced, however, of its absolute safety. How any one can even accidentally kill an animal with the Leduc current, which is employed in this work, is incomprehensible to me. If the technic is finally developed so that the current will be available for clinical use it will be the safest enesthetic of which we now have knowledge. Even as it is today I would not hesitate to submit myself to the current, provided it be administered in the same way and carried no further than in our laboratory experiments. Dr. Rabinovitch used 6 to 10 volts and one and a half to two milliamperes, with a direct current interrupted six to twelve thousand times per minute. In the morphinized animals we used only two volts, 2/10 milliamperes and six thousand interruptions per minute.

The sequestration method of Dawbarn should receive a more thorough trial than it has been given. According to this procedure, the patient is thoroughly anesthetized, after which the thighs are corded, thus cutting off this amount of blood from the brain. The patient is then placed in the sitting posture, and the operation continued, either with or without an anesthetic, or with a very small amount. In fifteen minutes from the commencement of the anesthesia the cords are gradually loosened. I had the honor to assist Dr. Dawbarn in one case, which was most successful in every way. The doctor would operate for at least ten or fifteen minutes, when a few drops of the anesthetic would be given and the operation continued. Pulse, respiration, color, and reflexes were all that could be desired. The only contraindication to this method, according to Dr. Dawbarn, is a weak heart. He uses it especially in operations on the face and neck. He considers it perfectly safe, for if any untoward symptoms should arise, the anema of the brain upon which this anesthesia is dependent, could immediately be rectified by placing the patient in a horizontal, or if necessary, in the Trendelenburg position.

I use a modification of this method daily in the following manner: As the surgeon is completing the operation by sewing up the wound, I stop the anesthetic, and at the same time raise the head of the table slightly. Pillows are placed under the patient's head immediately upon being returned to the bed. This procedure lessens slightly the amount of anesthetic given. It also allows any mucus or saliva to drain away from the upper respiratory passages and olfactory nerve, where, if it remained, it would cause nausea and vomiting. The sequestration method should be developed as a modification of other anesthetics or modes of administration, and this will probably be its future place.

Anesthetic Shock: Anesthetic shock is something seldom touched upon, yet it is safe to say that over fifty per cent. of surgical cases are shocked before they reach the table or during the induction period of the operation, or afterward from an overdose given sometime during the administration. Anticipation of the unknown and therefore to-be-dreaded effects of the anesthetic produces some of the symptoms of shock in the vast majority of patients, but fortunately in over 99 per cent. of these cases the symptoms disappear when the third stage, or surgical anesthesia, is reached.

We have the history of a patient in whom the psychic element predominated to such an extent that he died from fright one hour before the time for the operation.

Hewitt of London gives the history of a patient whose dread of the anesthetic was such that before starting the narcosis water was dropped on the mask for a few minutes; but even this procedure did not avail and the patient died before a single drop of chloroform touched the mask.

Two similar incidents have recently come under my notice. In one a patient at Bellevue Hospital in New York City cut his throat in anticipation of an operation which was to be performed the following day. The other incident was related to me by a physician in whose practice it happened. The patient was on the table and had been given a few breaths of nitrous oxide gas, when he jumped from the table, fled from the room, and had not been seen by the doctor since. Such incidents should serve to impress upon surgeons the fact that all patients need preliminary treatment, both mental and medical, in order to eliminate the psychic element. It is interesting to note that the cases above mentioned were all men. In my experience they are the patients who exhibit this mental depression.

Preliminary medication should consist of morphine alone, morphine and hyacine, morphine and chloretone, or an enema of 1 oz. of whiskey and 7 oz. of saline solution. Children, old persons, the insane, the feeble-minded, obstetrical patients, and individuals in a state of coma are the only ones who, in my judgment, should be excluded from the list.

Morphine: In 1909 I sent out a reprint entitled "Mixed Narcosis," in which I advocated morphine to precede nitrous oxide gas and oxygen. In this article I stated four general rules for the administration of morphine, which are as follows: (1). Whenever morphine is to be given, it always should be given before, instead of after, the operation, in order to obtain the benefit of this drug in the induction and maintenance of anesthesia. (2). All athletes and alcoholics should have this preliminary dose of morphine. (3). In extremes of life, the very old and the very young, if morphine is given at all it should be administered with very great caution. (4). Whenever morphine is administered a lighter narcosis should be maintained than when this drug is not employed. Out of 200 replies to the question asked as to whether the readers agreed with my views concerning preliminary medication, and also with the four rules regarding morphine, only two were negative.

In addition to the cases cited above, we must not forget that in over ninety per cent. of fatalities occurring in the early stages of anesthesia the patients have been men in robust health, requiring but a slight operation. In the light of these statistics it is almost criminal to place an alcoholic or an athlete upon the table without endeavoring to eliminate this psychic element; also to abolish the physical control which enables them to force the poisonous blood from the lungs to the heart. The percentage of deaths from the attempt to operate under morphine and scopalamin, or hyacine alone, or supplemented only by a few drops of ether or chloroform is so great that this practice will never prevail; but the very fact that morphine has been administered in such extremely large doses, and in all classes of surgical cases; should awaken us to the fact that the objection to small physiological doses of morphine before an operation is more academic than real. When given thirty minutes beforehand and properly modified according to the age, size, and condition of the patient, I have never seen or heard of the morphine doing harm. On the other hand I have known many patients to suffer from lack of this preparation.

The vomiting center is physiologically situated between what are commonly known as the first and second stages of anesthesia, that is between the second stage and surgical narcosis with complete muscular relaxation. If the induction period is unnecessarily delayed this center will be "found." It may or may not be preceded by sneezing or coughing. In the midst of an operation, in attempting to lighten the anesthesia, it may manifest itself also to the discomfort of the anesthetist. Again, in coming out of the anesthetic, as this center is passed over, unconscious vomiting may occur.

With small doses of morphine given sufficiently ahead of time to obtain the desired effect, none of these things are liable to occur. The whole nervous system is obtunded; especially is this true of the olfactory nerve endings in the respiratory passages. The patient takes more kindly to the anesthetic, passing quietly and quickly into full surgical anesthesia.

If, during the operation, it is possible to ease up on the anesthetic without disturbing the surgeon, the patient can be held between light and deep narcosis without once disturbing the dangerous vomiting center. The patient comes out, as a usual thing, without either conscious or unconscious vomiting. The kidneys and lungs have also been saved unnecessary irritation by reducing the amount of pulmonary anesthetic one-third to one-half.

Finally, the anesthetist is able to discontinue the anesthetic much earlier. The patient usually continues to sleep, or rather doze, from the morphine given, for from a half to one hour after the effects of the pulmonary anesthetic have worn off. The acute pain from the operation is thus minimized and the necessity of an after dose of morphine is not so great.

One to two quarts of normal saline solution per rectum materially mitigates the thirst which arises from the morphine, assists the kidneys, and brings the patient out in far better condition than when this is neglected. This should be given as a routine practice, and for the special purposes here mentioned while the patient is still in full surgical anesthesia. A slight Trendelenburg position assists greatly in the retention of the fluid.

If the post-operative condition demands a sedative, an enema of one ounce of brandy and seven ounces of saline solution will have the effect of quieting the patient, and with much less danger of the nausea than frequently follows the repetition of morphine.

The average dose is 1/6 to ⅛ gr. morphine, with 1/150 gr. atropine for women, and ¼ to 1/6 gr. morphine, with 1/100 gr. atropine for men. In one of the large hospitals one-fiftieth to one-hundredth gr. of atropine is used without the morphine as a preliminary with beneficial results.

Atropine is especially indicated as a preliminary when chloroform or ethyl chloride is to be used, as it maintains the respiration, and with ethyl chloride prevents profuse salivation, with consequent nausea and vomiting.

Morphine is even more strongly indicated before local anesthesia and spinal analgesia than in pulmonary narcosis. In my opinion it is, in a certain measure, at least, an antidote to cocaine. While this is not generally accepted, I have seen enough experiments with guinea pigs to convince me that such is the case.

The latest and best development in pulmonary anesthetics is the use of oxygen and nitrous oxide gas, supplemented by small amounts of ether and chloroform. There is now in the market a Hewitt appliance, a White dental gas oxygen apparatus, a Brown anesthetizer, and a Teter apparatus, the last two from Cleveland, Ohio. My own gas-oxygen apparatus is a modification of Hewitt's, having an additional valve for the admission of air, and also to-and-fro breathing. It has been found that 80 per cent. of all the surgical cases can be anesthetized with this combination.

Rectal Anesthesia.—Complete narcosis by this method was first mentioned by Pirogoff in 1847. The early experimenters used first a pure ether, then a mechanical mixture of ether and water, and later a vapor generated by placing a vessel in warm water. The after effects and some fatalities from these crude methods resulted in its abandonment. It was resurrected by Dr. Cunningham of Boston in a paper calling the attention of the medical world to the fact that by the use of air as a vehicle for the ether vapor colonic anesthetization was possible and also safe. Dr. Noel B. Leggett of New York City modified and improved Cunningham's apparatus, and was the first to conduct a series of experiments on the lower animals. With the knowledge thus gained he successfully anesthetized fifteen or sixteen cases in the Roosevelt Hospital.

To Dr. Walter S. Sutton of Kansas City belongs the credit of fully perfecting this method of narcosis. This was while he was an interne in Roosevelt Hospital. The essential points of his technic are: (1) A mercurial manometer to prevent too great pressure within the colon. (2) A generator for the accurate admixture of oxygen and ether. (3) Two separate tube systems, one for conveying the vapor into the colon and one for withdrawing excess vapor, and also for trapping any solid or semi-solid excreta. (4) The whole apparatus so arranged that it is controlled by the anesthetist who sits at the head of the table, being thus in a position to observe the patient and to modify the anesthetic as required. Dr. Sutton reports 140 satisfactory cases with no untoward results. Definite intestinal lesions are, according to him, the only contraindication to this method.

The colon is thoroughly cleansed by a castor oil purge at night, followed the next morning by three or more high soapsuds enemata, given one and a half hours apart, to be repeated until the return is clear.

The anesthetic is always started by the pulmonary method and continued by the colon after the patient is placed upon the table. A pressure of 20 mm. is constantly maintained in the gut.

Unless the patient is already suffering from some respiratory embarrassment this method possesses no advantage over my own of giving the vapor through a tube placed either in the mouth or in the nose. The anesthetist sits at the head of the table in either case.

Vapor Anesthesia.—The vapor method consists of passing air or oxygen through the anesthetic to be used, thus conveying a known percentage to the patient. It was first employed by Dr. Snow in 1849. Junker's inhaler, brought out in 1867, is probably the best known. Dr. Braun of Leipsig modified Junker's inhaler so that either chloroform or ether alone or any combination of the two drugs may be given. My own modification of Dr. Braun's apparatus consists in: (1) Giving the patient the vapor warmed to the temperature of the blood and passed through hot water, or a hot, neutral, volatile oil.

(2) A bent tube in the ether and hot water bottles so arranged that a warm concentrated ether vapor is possible. The chloroform vapor in my own inhaler, as in Braun's, is known, and the vapors of chloroform or ether may be given alone or in any desired combination.

In operations upon the head and neck the vapor may be passed through a tube and an even narcosis easily maintained without in any way interfering with the surgeon. Oxygen can be substituted for air whenever necessary. The narcosis by this method is much safer than by the drop method. Less anesthetic is used and the patient comes out of the anesthetic with little or no nausea or vomiting. The apparatus as now perfected can also be used for rectal anesthesia.

Spinal Analgesia.—This method has proved its unquestionable utility. While it will never supplant pulmonary anesthetics given by modern methods, in certain selected cases and under special conditions it is of the greatest value and will always have a permanent place in surgery. Introduced by Bier in 1899, mistakes of operators at that time have since been corrected, and the technic is now so far perfected that results compare favorably with those of other methods. Bier and Tuffier are using it constantly in Berlin. Professor Arthur Barker, University College Hospital of London, is using it in all suitable cases. It is also being employed in the Hospital for Sick Children, Great Ormond street, London.

By preliminary medication with morphine, nervousness, physical and psychical pain, the duration of anesthesia, the sense of heat and cold, nausea, vomiting, acceleration of pulse, rise of temperature, and headache, either during or after the operation, are in a very great measure overcome. The danger from the drug itself has been met by using tropococaine, or some other substitute for cocaine, and by the preliminary use of morphine and atropine, bromides, or hyoscin and nitroglycerin.

The extent of the analgesia is determined by the dosage and the position of the patient in the horizontal, the Trendelenburg, or the latter position reversed.

The following points are in favor of the method: (1) The patient assists by coughing, as when mucus or blood is in the throat, or in herniotomy; (2) the speedy action of the agent, analgesia usually being secured in from three to ten minutes; (3) the services of an assistant are rendered unnecessary. The above is particularly applicable in emergency, military and naval surgery. A further advantage is the utility of the method in children. Over 90 per cent. of a large number of cases in which Bainbridge has operated under spinal analgesia have been in children from four months to fifteen years of age.

Chloroform and Ether.—Neither of these drugs should be administered without being prepared to switch if necessity demands a change. If chloroform be used it should be warmed by placing the receptacle from time to time in a basin of hot water. It should also be preceded by the hypodermic administration of atropine 1/150 to 1/50 gr. thirty minutes before the operation. This prevents the imperceptible breathing that is sometimes so alarming when chloroform is administered alone.

Chloroform is contraindicated as a preliminary anesthetic when the psychic element is present. It is usually given as a sequence to ether. Employed in this way, it is not attended by the same degree of danger as when administered in the beginning of the narcosis. It is also perfectly safe with the patient in the Trendelenburg position.

Ethyl Chloride and Nitrous Oxide Gas.—Ethyl chloride is used for alcoholics and athletes, and for the obese, and is better than nitrous oxide gas in these special cases. It does not compare with nitrous oxide gas in point of safety. The combination of nitrous oxide gas, oxygen and ethyl chloride has not as yet been used clinically, so far as I know, except in few cases. I have experimented in the laboratory with it and find it perfectly satisfactory and absolutely safe. In fact, it is almost impossible to kill an animal with this combination. I have intentionally carried the anesthesia to the fourth stage in several instances, but have never failed to resuscitate the animal.

The time is over-ripe for the making of a change from the foolish custom of allowing interns in our hospitals to give anesthetics. It is unjust both to the patient and to the intern. There should be one or more paid anesthetists attached to every hospital, and the times for operations so arranged that all anesthetics are given by or under the direction of these experts. It is difficult to understand the mental attitude of some of our great surgeons who, while rebelling at the custom of allowing incompetent men to engage in this work, go to the other extreme of allowing nurses to administer, in a routine way, some particular anesthetic, usually ether. The weak and strong points of all anesthetics are known, and certainly it is wrong to fit the anesthetic to the anesthetist instead of to the patient.

No patient should have a general anesthetic when a local anesthetic can be satisfactorily administered. It is remarked by a competent authority that at least 25 per cent. of all surgical cases can be operated upon under local anesthesia. Nitrous oxide gas and oxygen can be *satisfactorily* given in 30 per cent. of all cases, and these patients should have the benefit of this non-poisonous anesthetic whenever possible. No patient should be given a pulmonary anesthetic when for any reason it is contraindicated, or when a previous administration has left him in a debilitated and uncomfortable condition. Preference should be given to rectal, local, spinal, or morphine anesthesia, or the sequestration method, employed singly, in combination, or in sequence. If, after a pulmonary anesthesia is begun, the patient is not doing well, it is safe to switch to morphine alone, or to any of the methods mentioned above.

Finally, by a judicious selection of a sequence of anesthetics and a combination of the same, by proper preliminary medication, treatment on the table and after-treatment, we are able to assure every patient that so far as this part of the operation is concerned he will leave the table in as quiet and natural a state as before the induction of anesthesia.

124 East Sixteenth Street.

THE RESIDUAL APPENDIX.

By OLIVER C. SMITH, M.D.,

HARTFORD, CONN.

SURGEON TO THE HARTFORD HOSPITAL.

By the residual appendix is meant the appendix vermiformis or a portion of it remaining following: (a) appendical abscess, which may have been operated upon by incision and drainage, or may have remained unoperated, the pus having been absorbed, or discharged without operation, or, (b) general or spreading peritonitis due to appendicitis, when drainage only has been performed.

The subject is but little referred to in the textbooks, but our attention has been called to it a few times in the current literature during the past two years. An incident occurring recently in the writer's work where a supposed residual appendix was found and removed during the course of operation for ventral hernia one year subsequent to the opening of the appendical abscess, the surgeon in this case, a man of large reputation, having been quite positive that he removed the appendix at the primary operation, and the writer and his associates equally positive that they removed it at the secondary operation, has led me to present this subject. The points which I wish to dwell upon are as follows:

(1) When is it desirable to remove and when not to remove the appendix in operating upon appendical abscess or general peritonitis due to appendicitis? (2) In what proportion of abscess cases is the appendix removed? (3) In what proportion of cases where it is not removed does inflammation, either acute or chronic, recur? (4) Should we in all cases where there is not some prohibitive contraindication advise the removal of the residual appendix at a secondary operation? (5) If a secondary operation is to be performed, how soon after the primary operation should it be advised? (6) The importance of the surgeon who operates primarily stating explicitly what he has done. (7) The importance of protecting the primary operator from unfair criticism. The recent literature bears the following upon the subject:

Dr. George C. Ross, in the Transactions of the Philadelphia Academy of Surgery, at the meeting of November 2, 1908, published in the *Annals of Surgery*, February, 1908, page 276, stated that he had recently operated upon three cases of residual appendix, in two cases the operation being for acute attacks, while the third was for the relief of a persistent abdominal sinus. The second case was operated upon three years subsequent to his first operation, when the abscess was opened and drained at a large metropolitan hospital, and he was told that the appendix had been removed. The third case came to operation nine months following the opening and draining of an appendical abscess. A discharging sinus persisted, and although the record stated that a gangrenous appendix had been found and removed as a slough, yet at this second operation one inch of the proximal end of the appendix was found continuous with the cecum. Dr. Ross concludes that as long as any portion of the appendix in communication with the cecum remains, recurrent attacks of appendicitis are to be feared. He quotes Sir Frederic Treves, who states that out of one hundred cases of appendical abscess which came under his notice, sixteen had recurrences and eight subsequently had the formation of inflammatory exudates in the right iliac fossa, no doubt of appendical origin. Twenty-four per cent. of Sir Frederic Treves' cases had recurrence after operation. Rose quotes Williams in the *British Medical Journal*, 1907, who cites a curious incident of an acute inflammation in an appendix entirely separated from the cecum. The author goes on to say the large majority of surgeons heretofore have taken the position held by Dr. Deaver that it is advisable to remove the appendix whenever it is not so situated in the wall of an abscess that to remove it would be to spread infection over the general peritoneal cavity.

Dr. Stewart McGuire, at a meeting of the Southern Surgical and Gynecological Association, December, 1908 (published in the *Journal of the American Medical Association*, January 16, 1909, pp. 241), referred to a former article entitled "An Analysis of the Last 500 Cases of Appendicitis Operated on at St. Luke's Hospital," in which there were twenty-three cases of appendical abscess of the class adherent to the parietal peritoneum. In this group of cases the treatment had been simply incision and drainage, no effort being made to locate or remove the diseased appendix. In every instance the patients were told that the operation was not for appendicitis, but for an abscess, which was the result of the appendicitis, and that the appendix had not been removed. Two methods of investigation were followed: first, the opinions and practice of a number of eminent surgeons were obtained; and, second, the twenty-three patients whose cases were reported were written to and their subsequent histories ascertained. From the two lines of investigation the following conclusions may be drawn: While the surgeon may be justified in advising a secondary operation in all cases, as theoretically the safest plan to follow, he is not justified in persuading, urging, or starving a patient until he consents to have it done. The appendix should always be removed at the first operation if the abscess is small and not adherent to the abdominal wall beneath the incision.

It should be left only in neglected cases in which the abscess is large and attached to the parietal peritoneum. When this condition exists the appendix is usually gangrenous, undergoes liquefaction, and is eliminated with the discharges. In such cases suppuration continues as a rule for several weeks, and before a secondary operation could safely be done the patient is homesick, weakened physically by confinement, and depleted financially by the expenses incident to the stay in the hospital. Experience seems to show that if subsequent trouble develops the infection is not usually acute, and pus, if it is formed, is walled in by old adhesions. Therefore, the surgeon does his duty if he makes it clear to the patient that, owing to the complications which existed it was not safe to remove the appendix, and tells him that while a second operation is advisable it is not imperative, unless he has tenderness over the incision, colicky pains in the bowels, or persistent digestive disturbances, in any of which instances it is distinctly necessary for him to promptly seek surgical assistance.

An article by H. S. Clogg of London on the advisability of removing the appendix at the time of opening the appendicular abscess was published by the London *Lancet*, March 6, 1908. The paper deals with one hundred and thirty-one cases of localized appendicular suppuration. In twenty-three the appendix was removed at the time the abscess was opened, and in one hundred and eight it was not removed. Of the one hundred and eight cases carrying a residual or remnant of residual appendix, one died of portal pyemia, three had subphrenic abscess, two of which proved fatal. One had diffuse peritonitis, eighteen suffered from prolonged abdominal sinus, one from recurrence of suppuration after closure of the sinus, eleven had recurring nonsuppurative appendicitis. In forty-two cases out of the one hundred and eight, disease in the appendix recurred, four of which were rapidly fatal, fifty-four of the patients reported that they were well as regards their operation for appendicitis, and twelve could not be traced. It is quite possible that of the fifty-four well at the time of writing, others may have subsequent trouble. This author naturally

concludes that the appendix should be removed at the primary operation if possible and at all consistent with safety, and that, if it is not removed at time of primary operation, it should be later.

In the experience of the writer and his associate, Dr. George N. Bell, in a series of 1,000 operations for appendicitis, of which records have been kept, there were: Operations for appendical abscess in 99, or 10 per cent of the entire number; operations for general peritonitis and free pus in 128, or 13 per cent of the entire number; the appendix was found gangrenous in 54, or 54 per cent of the abscess cases, and in 80, or 62 per cent of general peritonitis and free pus cases; the abdomen was opened and drained without removal of the appendix in 40, or 41 per cent of the abscess cases; the abdomen was opened and drained without removal of the appendix in 15, or 11 per cent of the general peritonitis and free pus cases; the appendix was removed by subsequent operation in 18, or 45 per cent of the abscess cases; a residual appendix was removed because of recurrence of appendicitis in 6, or 15 per cent of the abscess cases; a residual appendix was removed because of persistent fistula in 1, or 2½ per cent of the abscess cases. Of these 18 secondary operations 17 recovered, and one, a delicate, nervous girl, who was operated upon three weeks after the primary operation, died at the end of thirty-six hours, probably of shock and hemorrhage, the operation being exceedingly difficult, the adhesions not having been absorbed, nor had the suppurative process entirely subsided. The last operation of this series, where a residual appendix had given rise to a fresh attack, occurred in a male of thirty-four years, who four years previously had been seriously ill for weeks from appendiceal abscess which ruptured and discharged by the bowel. Four years later, following a typical onset of appendicitis, he developed a large appendiceal abscess which we opened, and floating free in the pus of the large cavity was a gangrenous appendix, 10 cm. long, containing a large concretion.

Returning to the propositions enumerated:

(1) When is it desirable to remove and when not to remove the appendix in operating upon appendical abscess? To the author it would seem that in cases of free pus without limiting walls of adhesions, if the patient's condition will warrant, a decided effort should be made to remove the appendix. If there is a well-defined abscess and the appendix is free, or if it forms a portion of the wall of the abscess, the abscess being adherent to the peritoneum, and can be easily separated from its adhesions, it should be removed. On the other hand, if its removal entails breaking through the walls of adhesions with the attendant danger of general peritoneal infection, or if manipulation provokes serious hemorrhage, or if the patient's general condition is such that further operative procedure will not be well tolerated, it is considered, I believe, by most operators, wiser to be satisfied with what has been accomplished, but in this connection each case will be a law unto itself. There can be no fast and fixed rule, and in some cases will one's judgment be severely taxed.

(2) In what proportion of abscess cases is the appendix removed? Statistics are not complete or convincing in this regard. In the author's cases about 41 per cent were not removed.

(3) In what proportion of cases where it is not removed does inflammation, either acute or chronic, recur? We have seen in the cases of Sir Frederic Treves that 24 per cent had either acute or chronic inflammation. In Clogg's 108 cases, about 40 per cent. had recurring trouble, and in the author's series 15 per cent. had recurring trouble. These figures will give some idea as to the frequency of inflammatory recurrences in the residual appendix.

(4) Should we in all cases where there is not some prohibitive contraindication, advise the removal of the residual appendix at a secondary operation? In the light of our present knowledge upon this subject it seems to me that there is no doubt it is our duty to advise a secondary operation in each case, otherwise we assume unnecessary responsibility, and in the event of recurring trouble one could but regret that he had not given such advice. The liability to the occurrence of a ventral hernia should strengthen us in this opinion, for a certain proportion of drained cases will necessarily be followed by hernia, and at the time of removal of the residual appendix the wall may be strengthened. In our early work most of us felt that after a suppurative appendicitis the appendix had done its worst, and there was little further to be feared from it. We satisfied ourselves with the expression that the appendix had probably "sloughed away and become lost in the discharge." While that is occasionally true those who have seen the residual appendix in numbers of instances realize that it is probably an exception.

(5) If a secondary operation is to be performed, how soon after the primary operation should it be advised? Surgeons differ in this matter, a few insisting upon the patient remaining in the hospital until the second operation is performed, fearing if he goes out he will not return. Others postpone it for several months. Undoubtedly sinuses and adhesions clear up much more quickly in some than in others. The local and general condition of the patient must be taken into consideration. If the mass, which could be felt before operation, has subsided, the sinus has healed, and the patient's general condition is favorable, and six to eight weeks have expired, there can be no objection to its performance at that time. If there is still some tumefaction or a discharging sinus, or the patient has not regained strength following the first operation, it is better to give the case further opportunity for convalescence. If the sinus persists, however, that in itself will be an indication for the operation. We have been happily surprised to find that at the expiration of six to eight weeks large masses of exudate and adhesions found at the primary operation have been absorbed, and the secondary operation is comparatively simple.

(6) The importance of the surgeon, who operates primarily, stating explicitly what he has done. Unless the surgeon is positive that he has removed all of the appendix he should say so frankly to the family or patient, and state his reasons for leaving a portion or all of the appendix. It is not a matter to be ashamed of, nor to be concealed. If he is even in doubt as to what he has removed being a portion of the sloughing or broken down appendix, he should state that doubt.

(7) The importance of the surgeon who operates secondarily of protecting the primary operator from unfair criticism. If the surgeon operating upon the residual appendix—the primary operation having been performed by another, and if the appendix is found, it is better not to make the statement until the first surgeon has been conferred with,

and it should be made plain to the family or patient by the surgeon at this time that it is a highly proper procedure to drain an appendical abscess without removing the appendix, that it is done by the best of surgeons, and undoubtedly was the proper procedure in this case. If we are all careful to pursue this course it will avoid unpleasant complications and unfair criticism.

From our knowledge of the pathology of appendicitis and the comparative frequency with which appendicitis recurs sooner or later following an appendical abscess or general peritonitis caused by appendicitis, we must conclude that the residual appendix is much more subject to inflammation than the appendix which has not been diseased. If its mucosa is continuous with the cavity of the cecum it is still exposed to infection. In addition to that, its circulation has usually been partially destroyed, it has become adherent to the abdominal wall, or some other organ, and is in a position to be strained or traumatized. Moreover, there may be residual concretions and residual pockets of pus within the lumen which did not escape at the primary attack. If these deductions are correct there can be no doubt of our duty in advising a secondary operation, and explaining thoroughly to the patient the reasons for, and the advantages of, this procedure.

REPORT OF THE TREATMENT OF TYPHOID FEVER WITH VACCINE.*

By AUSTIN W. HOLLIS, M.D.,

NEW YORK.

VISITING PHYSICIAN TO ST. LUKE'S HOSPITAL.

During my service at St. Luke's Hospital in the late summer and fall of 1909, I began the treatment of all cases of typhoid fever with vaccine. A review of the literature at that time showed the treatment to be still in the experimental stage, with doses ranging from 1,000,000 to 300,000,000 dead typhoid bacilli, and no uniformity as to the repetition of the dose. In our cases the dose was given subcutaneously in the region of the buttocks every second or third day, each dose being either 10 or 50 million dead bacilli. During the summer and fall we had 37 cases of typhoid fever; some of these cases occurred in the service of Dr. S. W. Lambert, and, being of the same season, are introduced for comparison.

Twenty-one (21) cases were treated by the older method of hydrotherapy, either by the tub bath or sponging.

Eleven (11) cases were treated with vaccine without hydrotherapy.

The remaining five (5) cases were too short a time under treatment to make any comparisons.

The diet in general, especially in the hydrotherapy cases, was of the high caloric variety. No drugs were employed, but strychnine and whiskey were used as stimulants in the severe cases. The bowels were moved by enemata.

The cases which were treated by hydrotherapy, barring a few which were given sponge baths because of poor response to tubbing, had a tub bath from 80° to 90° for 15 minutes with friction every four hours from noon until midnight inclusive if the rectal temperature was 103° or higher. At 8 A.M. all received a warm soap and water sponge.

*Read before the Medical Section of the Academy of Medicine, March 15, 1910.

Those treated by vaccination received no baths other than a daily warm soap and water sponge. In a very few cases 250,000,000 bacilli were employed but no different clinical or laboratory effect could be noticed between the smaller and larger doses. No fever reaction was obtained. No case ended by crisis. Occasionally a slight local erythema or itching was noticed at the point of injection, which cleared up without treatment. The agglutinins were markedly stimulated by the vaccines. Complete agglutination was frequently observed in dilutions as high as 1-500 to 1-1000, while cases without vaccines showed incomplete agglutination in 1-80 dilution. The febrile course in a few cases seemed shortened, but the abrupt change from the sustained fever to the amphobolic type seemed hastened by vaccination, averaging 17.1 in the cases treated by vaccines, and 23.2 in those getting tub baths.

The average day of admission from the beginning of the first symptom was 11.3 and 13.8; of defervescence 36.7 and 34.3 for the vaccination and hydrotherapy cases respectively. The temperature averaged equally high in both series. Hemorrhage was seen with equal frequency, though not so severe, in the vaccinated cases. Relapses were noted with more frequency in the vaccinated cases—30 per cent. as compared with 10 per cent. Relapses were in all cases mild. The cases which received vaccine were in no way selected.

No death occurred in the vaccinated cases; four occurred in the other series, one from hemorrhage one from toxemia, one from perforation and one from pulmonary thrombosis with necrosis of the whole left upper lobe of the lung.

Headache, gastrointestinal symptoms and toxemia were far less frequent in the vaccinated series than in the other cases, and the absence of discomfort seemed striking, while convalescence was more rapid.

A comparison of possible value of the effects of vaccine may be made in three cases which occurred in young adults of the same family in the better class of life who apparently were infected by oysters at about the same time.

The first, a robust man of 26 years, entered the hospital about five days before the other two. He received tub baths throughout his illness; he was profoundly sick; his temperature held at 104° to 105° for 39 days before assuming the amphobolic type; the latter stage of the disease was associated with severe chills and violent temperature reactions, once or twice reaching 107°, which probably came from a cholecystitis; he defervesced on the 62nd day and made an uninterrupted recovery.

The other two cases, husband and wife, entered the hospital together. The man, 33 years, also robust, had a temperature of 104° and marked toxemia; on the sixth day of his disease he received 50,000,000 dead bacilli injected subcutaneously; the dose was repeated every other day until the 14th. The response was rapid; by the eighth day, still with temperature of 104°, he was bright mentally and clamoring for food and said he felt like getting up. On the 13th day the fever broke and on the 17th day was normal. A very large hard spleen did not diminish in size, and on the 20th day fever returned and he had a nine-day relapse of very mild type with fever as the only symptom. Vaccination was resumed on the 20th day, 50,000,000 dead bacilli being given every other day until the 32nd. Convalescence was very rapid and complete.

The third case, the woman, presented three seri-

ous complications. She was 4 months pregnant, had a history of a former dilatation of the heart and carried a weak pulse ranging from 120 to 150 throughout the course of the disease. She had repeated profuse nasal hemorrhages which were controlled with great difficulty. For a few days she was treated by sponge baths, but her reaction was poor and because of exhaustion they had to be stopped. Vaccine was then employed reluctantly, because personal experience was at that time very limited; but on the 10th day we started with 10,000,000 dead bacilli every other day and later raised the dose to 50,000,000. The temperature continued to hold at 104° to 105° for twenty-one days; she was exceedingly weak, but her apathy and toxemia disappeared very shortly after vaccination was begun. She was fearful of the epistaxis and the dangers of abortion. The fever was prolonged to the 47th day, but after the 21st it became quite moderate and she appeared in a convalescent stage. During February of this year she gave birth to a healthy boy.

A fourth case, whose chart I will hand around for inspection, occurred in the recent epidemic above 116th street. I saw her first in consultation with Dr. Almgren. She was stuporous, moaned from severe occipital headache, and the diagnosis was in doubt. She was taken to St. Luke's on the sixth day of her illness and given sponge baths, with icebags to head. It was not before the ninth day that positive blood reaction was manifested. On the tenth day 10,000,000 bacilli were injected and continued every other day. Response was very rapid, with marked amelioration of the headache, and nourishment was taken better. She rested quietly. In spite of the sponge baths her fever until the 10th day held very closely to 104° or a little over; but after the administraion of the vaccine it never went above 104° and soon entered the amphobolic stage. Defervesence occurred on the 24th day. Convalescence was rapid, but one day there was a temperature of 101°, due to an abortive otitis media.

Conclusions.—It would be absurd to assume any positive value from vaccine therapy in typhoid fever in such a small series of cases; it would be equally absurd to rely on the impressions even of an old observer as to the benefit of such treatment on the same series. When we hear reports that starvation diet and the high caloric diet are both highly successful in typhoid fever; when after years of experience one has adopted what seems to be a rational diet and returns to the hospital service to hear the house physician tell of the wonderful results of the "Coleman" or "Shattuck" feeding; when we read of the annual fights of the pediatrists over the high proteid and high carbohydrate diet in infant feeding we realize the difficulties of observation without prejudice. But when the answer is plainly written, as it was in the case of diphtheria antitoxin, although there may have been bitter differences of opinion in the beginning, yet in time those who got the answer first were vindicated by the truth of their observations.

In our experience in the vaccine therapy of typhoid fever we can claim that the agglutinins were markedly stimulated, and there were no harmful results.

Are there any theories that may be advanced to capture the intelligence in this treatment?

Cure in all disease due to bacteria is probably accomplished by the autoprotective forces of the blood. As far as our present knowledge goes, these diseases are all local infections; they may become general from multiple foci; bacteriemia may result but the blood stream itself is not the culture medium. Bacteria may be found in it, but never easily and usually by a difficult cultural process. In spite of the fact that of late years typhoid fever has often been spoken of as a general blood infection, there is no evidence to show that Peyer's patches and the spleen are not the early sites of bacterial growth, with other foci only as complications. In no sense may it be considered a blood infection simply because the blood may hold bacteria just as the urine may.

Fever is due to some specific reaction between living cells or their plasma and bacteria or other living organisms or their products. It is not due to dead bacteria or their products in artificial culture media. An effort has been made to prove fever a beneficial and necessary protective reaction; but that it is ever beneficial is extremely doubtful. The employment of antitoxin serum shows that fever is not an essential reaction in its curative action. The familiar vaccination in smallpox produces full protection by a local reaction, and not because of a febrile movement. The argument that it would seem useless, even harmful, to introduce into the system the bodies of dead bacteria to cure a disease which is constantly poisoning the host with living bacteria or their products is a very superficial one. We assume that the cure in bacterial diseases is by the autoprotective forces of the blood, stimulated by the bacteria of the same disease or their products.

In pneumonia the onset is usually with a chill from toxic absorption; a vast capillary surface is exposed, and the clinical signs are those of a violent toxemia; if the protective forces respond, they do so quickly and decisively. In typhoid fever action is similar but slower. In these diseases we do not know how many bacteria or how much toxin is being absorbed by the minute; we do know that up to a certain point the system can stand the harmful effects and that it is protecting itself. If we can artificially stimulate the agglutinins, the opsonins, the precipitins and antibodies by the injection of dead bacteria which do not increase the fever nor add to the patient's danger, then we can say that the use of vaccine rests upon a sound basis; but to get the best results a great deal more is necessary to know; we do not know how often it should be employed, whether the dose should be uniform, whether it should begin very early with a large initial dose, or with small and increasing doses. The argument that we should use much larger doses because antitoxin is now employed in much larger doses than in the beginning is altogether fallacious. That we use much smaller doses of tuberculin now than formerly may be more reasonably argued. It has been conclusively shown that billions of dead typhoid bacilli may be introduced into the well without harmful reaction; we do not know certainly whether the same holds good in the case of those suffering from the disease.

From theory alone I predict a brilliant future for typhoid vaccine as a protective as well as a therapeutic agent.

To Dr. William R. Janeway, my house physician, who prepared the statistics of this report and aided me in the treatment of the cases, I give my sincere thanks.

40 West Seventy-first Street.

HEMOPHILIA TREATED BY TRANSFUSION.

By MILTON HAHN, M.D.,

WASHINGTON, D. C.,

FORMER HOUSE-PHYSICIAN, MOUNT SINAI HOSPITAL, NEW YORK.

THE strange hereditary, hemorrhagic diathesis called hemophilia has been known for centuries, but its pathogenesis, and consequently its therapy, still baffle medical science. Of all the theories which have been proposed concerning the causation of this disease, the most tenable seems to be the one formulated by Sahli: that there is a chemical change in the blood vessel walls. The modern work on the coagulation of the blood, particularly the researches of Morawitz, has shown that the vessel walls secrete a substance, thrombokinase, or the zymoplastic substance of Schmidt. This activates the thrombogen contained in the blood plasma, forming prothrombin, which combines with the calcium salts to form thrombin, the fibrin ferment. Normally when the blood vessels are cut this substance is secreted by the vessel wall and clots are formed which close the mouths of the bleeding veins. But in hemophilia this secretion, according to Sahli, is lacking. This explains the fact that hemophilic individuals continue to bleed, although the coagulation time of the blood outside of the body may not be increased.

On the basis of this hypothesis it is rational to attempt to supply the missing substance by the use of normal blood. This principle in the treatment of the disease is not new. Normal serum has been used in these cases in various ways. It has been given by mouth, subcutaneously, and injected into the bleeding area. As early as 1874 Boisnot injected defibrinated blood into the vein of a boy who was suffering from uncontrollable hemorrhage, and who immediately recovered. These methods have achieved only partial success, and better results are promised by the direct transfusion of blood. Modern surgery has perfected the technique of this operation, making it a comparatively simple procedure. A few cases have been reported recently, most of them successful. The operation is a life-saving one. Whether it can effect a permanent cure of the disease is a question which can not be answered at the present time. The following case from the service of Dr. Henry Koplik, Mount Sinai Hospital, is of interest:

Hemophilia; Acute, Traumatic, Uncontrollable Hemorrhage; Severe Secondary Anemia; Coma; Transfusion; Recovery.—The patient is an Italian male child, one year of age. The parents are aware of the hemophilic tendency in the family, and give the following interesting family history: The mother of the patient had one brother and one sister, of whom the former died of hemorrhage, and the latter lost a son with hemorrhage following the extraction of a tooth. The patient also had a brother and a sister, and of these the boy died following an operation for cervical adenitis, while the girl bled for 36 hours after a slight injury to the teeth.

The patient was admitted to the pediatric wards of Mount Sinai Hospital on March 22, 1910. The past history is negative; he has never had any illness and has had no previous hemorrhage. A week before admission he fell against a chair, knocking out a tooth, and since then has bled continuously from the gum. On admission the patient was evidently suffering from severe anemia. The skin and mucous membranes were very pale, the child was restless and breathing rapidly, the pulse was rapid but of good quality. Examination of the mouth showed the left upper incisor tooth missing, and blood oozing from the cavity. The rectum was filled with hard black fecal masses, which on examination were found to contain blood. In addition the child showed some signs of ricketts; a rachitic rosary and somewhat enlarged liver and spleen. Otherwise the physical examination was negative.

The family history may be more clearly expressed by the accompanying diagram.

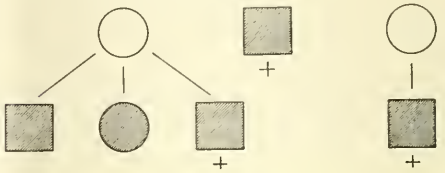

Diagram showing the family history of a case of hemophilia; the circles denote females, the squares males. The shaded figures indicate hemophilic individuals. The fatal cases are marked +.

This family history exemplifies the strong predilection of the disease for males. The single female affected had only a comparatively slight hemorrhage.

Examination of the blood on admission showed the following: R. B. C., 1,024,000; Hgb., 30 per cent. (Sahli); W. B. C., 5,000; Polynuclears, 51 per cent.; small lymphocytes, 31 per cent.; large lymphocytes, 17 per cent.; eosinophiles, 1 per cent.; coagulation time, 15 minutes. All efforts to check the bleeding were vain: local compression, application of diphtheria antitoxin, administration of calcium lactate, injection of sterile gelatin, etc. The apparent bleeding was very slight but continuous, and the child rapidly lost ground. On March 25, ten days after the injury, it was decided to try transfusion. At this time the hemoglobin had fallen to 11 per cent., and before the operation the child became comatose. The respirations were deep and rapid and of the Kussmaul type, the pulse rapid and feeble. It was feared that the child would die before preparations could be completed.

The transfusion was performed by Dr. Charles E. Elsberg, who used a modification of the Crile operation, which he has devised. The patient's father was the donor. The radial artery of the donor was anastomosed to the femoral vein of the child. The only difficulty encountered in the operation was in the exposure of this vein, the child's vessels being small and collapsed. The blood was allowed to flow for about fifteen minutes, and a marvelous transformation was observed. The waxen skin of the child became suffused with a red glow. Indeed, toward the end he became cyanotic on account of the injection of too much blood. At the same time the infant, who previously lay apparently lifeless, regained consciousness and began to cry. The hemoglobin rose from 11 per cent. to 90 per cent., and the coagulation time changed from 15 minutes to 7 minutes. The child remained in a semi-stuporous condition for two to three days, but after this rapidly improved. The coagulation time, which was diminished directly after the transfusion, again became lengthened. On March 28, three days after the operation, it was 18 minutes; on April 6, 12 minutes; and April 25, 9

minutes. There was no further bleeding, however, from the original site or from the operative wound. The hemoglobin remained high. On April 8 the blood examination showed R. B. C., 4,000,000; hemoglobin, 82 per cent.; on April 25, R. B. C., 4,400,000, hemaglobin 97 per cent. The child was discharged April 30, 1910, five weeks after transfusion, in excellent condition.

This transfusion was performed as an emergency operation on a moribund patient, and the result greatly exceeded our hopes. The child was suffering from a hemorrhage which we were unable to control, was completely comatose, had a pulse which was scarcely perceptible; and in a few minutes he would certainly have been dead. The immediate checking of the hemorrhage after transfusion and the rapid return to perfect health make a picture which it is seldom the privilege of the medical man to see.

STATISTICAL ANALYSIS OF OVER SIXTY-EIGHT THOUSAND CASES OF TYPHOID FEVER.

REPORT NO. II.

MORTALITY.

BY ABDULLAH K. SALLOM, M.D.,
PHILADELPHIA.

IN this second report it is my object to present briefly the typhoid mortality along the same lines laid down in my preliminary report (MEDICAL RECORD, Nov. 20, 1909). The study of mortality, and of typhoid fever in particular, is indeed interesting and instructive. In this case it reveals a truly remarkable condition of affairs, which I have attempted to represent graphically by the accompanying charts.

As I stated in my preliminary report, there occurred in Philadelphia from January, 1898, to June, 1909, sixty-eight thousand nine hundred and forty-three (68,943) cases. Of this number eight thousand one hundred and two (8,102) died, giving a mortality of slightly over 11.75 per cent.

The prevalence of typhoid fever, as we all know, is markedly affected by season, and very early in the study the question naturally arose, Is mortality also affected in the same manner? That season does play an important rôle cannot be doubted if we but glance at Chart I.

The unbroken line represents the average number of cases occurring during each month of the year. The percentage mortality is represented by the dotted line. The figures to the left of the chart refer to the number of cases, while the percentage mortality is denoted in the column on the opposite side.

Starting with a mortality of slightly over 10 per cent., it rises during February and March to 12.37 per cent. Falling during April, it ascends during May and June. The July mortality is phenomenal, reaching the maximum of 17.61 per cent. Dropping as precipitately as it rose, the mortality for August is only 11.75 per cent., and falls to 10.21 per cent. during September. For October it again rises, only to fall during November, and rise in December.

The relationship of morbidity to mortality is indeed striking. Starting in January with an average of nearly seven hundred, the number of cases rises during February and then gradually falls, reaching its lowest ebb during July. On the other hand, mortality, starting with a minimum during January, rises to reach its maximum in July. During September, in which month we have the second maximum in morbidity, a second minimum in mortality is obtained. The one salient feature which this chart shows to a remarkable degree is the apparent relationship of morbidity to mortality.

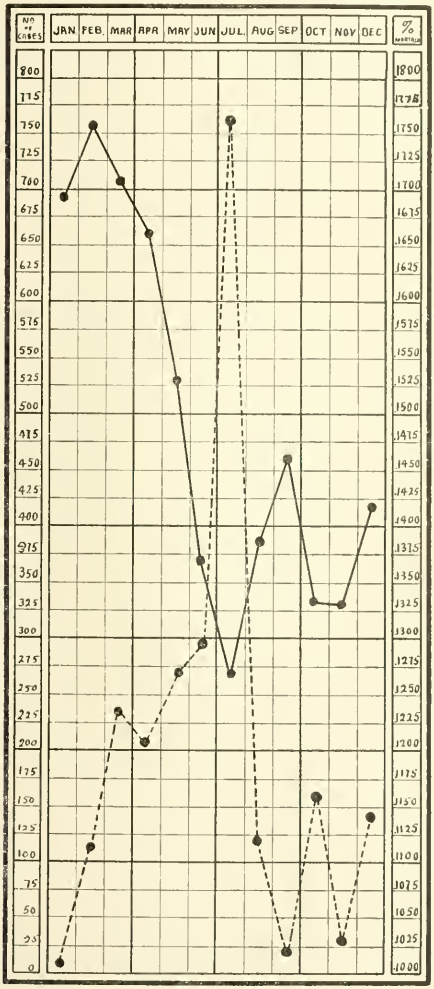

CHART I.—Showing average number of cases and percentage mortality of typhoid fever for each month of the year.

The importance of this condition from a prognostic point of view can hardly be overestimated, but a more careful study somewhat modifies the condition. We all know that typhoid fever is a

disease of from about four to seven weeks' duration. It becomes evident, therefore, that the majority of those dying in January will have contracted the disease in the preceding month. To

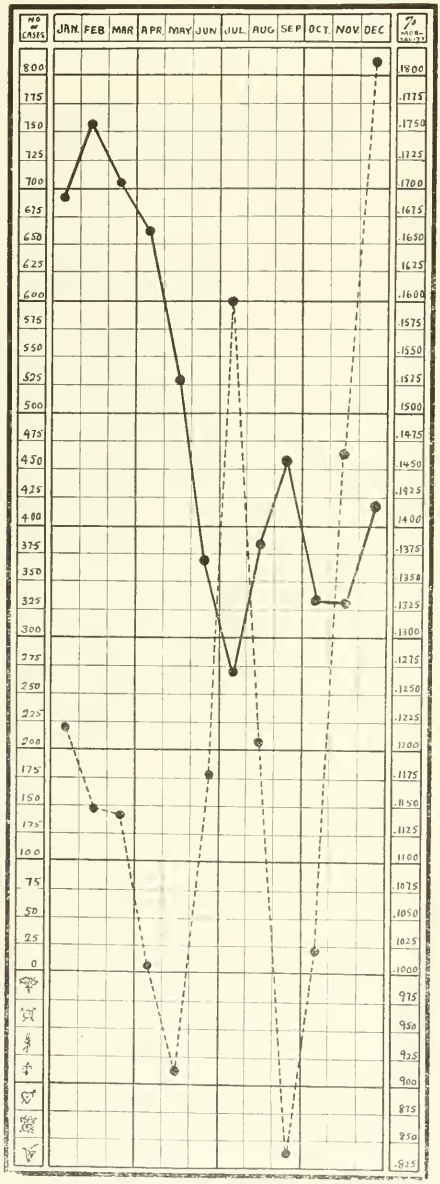

Chart 2.—Showing the average number of cases and the percentage mortality for each month, obtained by taking the mortality of the one month and the morbidity of the preceding month into consideration.

compute, therefore, the true percentage mortality for any one month the mortality of that month and the morbidity of the preceding month must be taken into consideration. Chart II is based on the percentage mortality obtained in this manner. At first glance this chart does not seem to show what the preceding chart does. Upon careful study, however, it collaborates it to a certain extent. It will be noticed that with the minimum morbidity of July the first maximum in mortality is present; and with the second maximum in morbidity occurring during September, the minimum in mortality is obtained.

Which of these charts shall we accept as representing the true percentage mortality? From the knowledge which I have gained by the study of these statistics I believe that season has a marked influence on typhoid mortality. Further than this, I prefer to leave it to the medical profession, to whom this report is respectfully submitted.

In conclusion, I desire to state that I hope in the very near future to submit further data upon the subject to prove definitely the validity of the following statement:

With the maximum morbidity a minimum percentage mortality is present, and vice versa; and further that as morbidity falls mortality rises.

1625 South Fifteenth Street.

Some Observations on Gastrointestinal Fermentation.—D. Sommerville says that there are two forms of fermentation: (1) the acid in the upper part, and (2) the alkaline in the lower part of the digestive tract, and mentions certain interesting facts which have come to light in the course of his experiments and observations. He says that it has long been known that where an individual consumes excessive quantities of protein, *i.e.* larger quantities than he can assimilate and finally oxidize, a more or less definite set of symptoms appears, characterized by headache, drowsiness, lassitude, and irritability; these symptoms are accompanied by an increase in the ratio of ethereal to preformed sulphates in the urine, as also an increase of the same sulphates to the total nitrogen (Amann's coefficient). Such a urine when subjected to a simple qualitative examination gives increased quantities of indol, indolacetic acid, phenol, skatol, and aromatic oxyacids, all products of intestinal putrefaction. The feces of such a patient when distilled and the distillate shaken up with a concentrated solution of mercuric chloride (Schmidt's reaction) yield the red color, changing to yellow fluorescence, indicative of hydrobilirubin, an index of reduction processes due to putrefactive bacteria. In this connection it may be noted that the variations in amounts of indol and phenol and their derivatives excreted in the urine and feces form a fairly accurate index of the degree of putrefaction going on in the intestine, since these substances are not formed in any other part of the body, nor through any other agency than that of putrefactive bacteria. This statement excludes, of course, any degree of putrefaction that may have been present in the protein food before ingestion. In health the amount of ethereal sulphates varies uniformly with the amount of protein consumed, and their ratio to the total nitrogen in the urine is approximately constant, viz., about 1.5:100. If carbohydrate be substituted for protein in the diet of such a patient, his physical and psychical attitudes towards men and things become quite changed. He loses his headache, becomes alert, and exchanges his irritability and moroseness for a more agreeable manner. Indol, indolacetic acid, and the aromatic oxyacids rapidly decrease, and in time completely disappear from his urine, whilst his hard, dark-brown, and extremely offensive feces give place at first to loose, but afterwards to formed soft grey and inoffensive material. Ethereal sulphates are always markedly reduced on milk diet, and the richer the milk in sugar the more marked the reduction.—*The Lancet.*

POLIOENCEPHALITIS.

A FEW years ago acute anterior poliomyelitis was considered to be a primary local degenerative disease of the anterior horns of the gray matter of the spinal cord. With the recent rapid growth of knowledge of this disease, however, it has become recognized that the local lesion in the cord is but the sequel of an acute inflammation which is in itself but a part, and in fact not a necessary part, of a general constitutional infection or intoxication. Not only has it been pointed out on many occasions that during epidemics of typical poliomyelitis cases occur showing constitutional symptoms which lead the observer to expect at any moment the appearance of the tell-tale paralysis, but are aborted so that the little patient after a few days' illness is again returned to robust health, but it has also been shown, first by Strümpell, and later by many other authors, that in such epidemics similar cases occur, but with the striking difference that the paralysis resulting is of a cerebral rather than a spinal type. To such cases have been given the name Strümpell's paralysis or polioencephalitis.

In *The Practitioner* for July, 1910, Reginald Miller of London briefly and ably reviews the present knowledge of this disease. Its occurrence in epidemics of poliomyelitis, in the hot season, and in children between six months and six years of age, and the complete similarity of the symptoms of onset to those of poliomyelitis leave but little doubt that in the two symptom complexes we are dealing with different manifestations of one and the same disease. Miller in fact groups all of these allied conditions as one infection with four clinical forms —acute poliomyelitis, acute polioencephalomyelitis, acute polioencephalitis, and the abortive form causing no paralysis. While the nervous symptomatology of the myelitis cases is comparatively simple, consisting of little more than a flaccid paralysis and more or less hyperesthesia, that of the encephalitis group of cases may be as varied as are the innumerable functions of the different portions of the brain tissue.

By polioencephalitis superior is understood those cases in which the virus of the disease has localized its activities to the cortex, causing hemiplegias or mental degenerations. Under the title of polioencephalitis inferior are grouped affections of the muscles of the eye, the facial, or the auditory nerve. Encephalitis cerebelli is characterized by a sudden onset of ataxia, making a condition most difficult to diagnose, as it may be associated with nystagmus and scanning speech, and thus be easily confused with insular sclerosis. Encephalitis of the mid-brain shows the chief symptoms of acute tremor, hypertonus, and spasticity. Thalamic encephalitis, pontine cases, and poliomyelitis bulbi have all been seen, as have also acutely fatal cases supposed to be due to involvement of the medulla.

From the etiology and gross symptomatology of all these varied conditions it is evident that they belong to one great disease, of which poliomyelitis is but one clinical group. The use of two different names for two manifestations of one disease is unfortunate and confusing. A new term is desired, and when it is obtained, it must be some comprehensive word, containing a specific reference to neither the spinal cord nor the brain, which will enable the grouping of all of these clinical complexities as one great disease.

TYPHOID CARRIERS.

To how great an extent bacilli carriers are a means of dissemination are responsible for conveying typhoid fever is a question which is yet quite an open one. There are those who assert that "typhoid carriers" are among the most potent modes whereby infection is spread, while others declare that the situation in this connection has been greatly exaggerated and that infected human beings are really a comparatively negligible quantity insofar as the conveyance of the malady is concerned. Perhaps, in this matter it would be wise to steer a middle course and it might not be presumptuous to state that "typhoid carriers" are capable of spreading the disease to a somewhat limited extent, but at the same time the danger from this source is a real one and that measures should be sought to nullify or to limit the scope of the menace.

Some interesting studies on the subject have been undertaken recently in Great Britain, notably by Dr. D. S. Davies, medical officer of Healtht of Bristol, Dr. Walker Hall, Bristol; Dr. E. Emrys-Roberts of Cardiff, and Dr. I. Fletcher of Manchester. These authors have been publishing in the *Lancet* from time to time their conjoint researches and conclusions on various phases of the typhoid carrier question. In the *Lancet*, September 3, are some further observations on the subject chiefly dealing with treatment. The claim has been made more than once that the typhoid bacillus can be successfully eradicated from the human tissues by certain means of treatment, but the authors are of the opinion, basing their views on experiments and their own experience, that these conclusions would be modified or withdrawn were the carriers subjected to more rigorous and continued examinations.

The main subject of the experiments in Bristol Infirmary was a woman who contracted typhoid fever in 1905 and has been a carrier since that time. The authors were unable to make any experiments upon the bactericidal or opsonic properties of the blood serum, and their observations were confined to the examination of the typhoid organisms in

feces and urine to the agglutinia contents of the serum, and to the action of therapeutic agents. The action of lactic acid bacilli upon *B. typhosus* and *B. coli* was tested and discussed and a summary of the results shows that while varying degrees of inhibition of coli growth were obtained, the inhibitory effects upon the typhoid bacilli was very slight, practically nil. This finding is in accord with the experience of those who have given the soured milk therapy a prolonged trial. Of course, in "typhoid carrier" cases, at times bacilli cannot be detected in the excretions, but they frequently reappear. Autogenous vaccine was used in gradually increasing doses for a period of five months with no definite success. Other drug treatment employed did not produce the desired effect, and on the whole the outcome of the experiments was negative and somewhat discouraging. The authors also conclude that the data already accumulated are insufficient to permit of the slightest attempt at generalisation or deduction as to the employment of the Widal reaction as a means of diagnosis of suspected carriers or as method for investigating the condition of convalescents.

Thus, the report so far is the reverse of encouraging, although the fact must be borne in mind that in the Bristol Infirmary the material was limited and that the experiments were in no respect wide enough to be conclusive. As said before, our present knowledge of "typhoid carriers" is very restricted in regard to their numbers. With regard to their menace as a source of infection, our knowledge, too, is vague. Several cases of typhoid fever have undoubtedly been traced to "typhoid carriers," but whether they are a fertile source of infection cannot be definitely stated. The matter requires far more careful study than has yet been given to it.

TRYPSIN THERAPY OF LOCAL TUBERCULOUS AFFECTIONS.

The treatment of tuberculous abscesses, hygromata, lymph nodes, etc., by proteolytic enzymes has now been studied systematically for two years or more and there is abundant evidence that the treatment often gives satisfactory results. The theories advanced to explain this action vary, but the most plausible is the following: tuberculous pus contains no proteolytic enzyme, so that the addition of one converts the albumin and albumoses of the pus into more soluble end-products of peptonization with resulting absorption. Various proteolytic enzymes have been employed, to wit, commercial trypsin, trypsin activated by admixture with charcoal, and the enzyme of the leucocytes themselves. It would appear that 1 per cent. trypsin solution gives as good results as any other form of enzyme (see the Vienna letter in the Medical Record of September 3.) The number of reports on this subject is relatively small when we consider their favorable character. So far as we know no unfavorable reports have been published.

Authorities have differed somewhat as to technique and to indications and contraindications. Brüning (*Deutsche medizinische Wochenschrift*, September 1, 1910) has been at great pains to introduce some degree of system into this subject, but his conclusions are somewhat antagonistic to those of other workers in the field. For example, others have pronounced the treatment absolutely inoperative in tuberculous bone abscesses, but the author finds trypsin of value in small suppurating foci in bony tissue. He agrees with others in finding it of value in cold abscesses, but limits its use to small stationary lesions. In burrowing abscesses he cannot see that it is in any way superior to iodoform-glycerin. In joint tuberculosis as well as in large foci in bone he finds it unsuitable. This is likewise true for caseous lymphatic glands. It seems a fair generalization that trypsin accomplishes nothing in caseous or proliferative lesions. The *sine qua non*, in other words, is a fluid or semifluid collection, in which the enzyme is able to render soluble that which has been insoluble. Naturally, enlarged lymph nodes, which have not yet become caseated, are not amenable to trypsin treatment.

The author's technique differs somewhat from that ordinarily laid down. He punctures the abscess outright with a trocar and evacuates it. The trypsin solution is then thrown in (some authorities have injected the ferment directly into the unevacuated pus). It doubtless acts by peptonizing the residue of old pus as well as newly generated pus. The author has treated over 100 cases of local tuberculosis in this manner. He repeats the injection at about weekly intervals if indicated. He has never encountered anaphylaxis or drug exanthem as a result of trypsin injections.

Without going more deeply into the matter, we may look upon the trypsin treatment of local tuberculous foci as at least on a par with the old iodoform absorption treatment. Most surgeons undoubtedly favor the most radical treatment of local tuberculosis. Many, we know, refuse to temporize or palliate in such matters. But along such lines there can be no advance. Progress and conservation are often happily allied, and this appears to be the case with the subject in question.

Staphylococcus Vaccine in the Treatment of Cutaneous Lesions.

Antistreptococcus serum has been used with varying success for some time by different practitioners. The nonsuccess in certain cases seems to have been due to the varieties of streptococcus that have been the causative agent, and successful results have been obtained only when the serum was made from the same variety as caused the suppuration. Vaccines of the staphylococcus made for each individual from his own peculiar germ have been used by A. Mauté in various forms of skin lesions caused by the staphylococcus, and the results have been in some conditions markedly successful. In *La Presse Médicale*, for June 22, 1910, Mauté gives an account of his observations. He had poor success as long as he made use of the so-called stock vaccines, but when he made autogenous vaccines his results were good. He gives the method of producing vaccines sterilized by heat and by the presence of a small amount of phenic acid. It is possible to obtain a vaccine in four days from the beginning of the process of manufacture. Injection is made into the subcutaneous tissue of the thigh, and causes no

general or local reaction. The dose varies with the affection that is to be treated, from 250 to 1500 million bacteria, and injections are made five or six days apart. No regard need be had to the opsonic index. The author's observations include furunculosis and pustular acne. In acne the results were somewhat inconstant, being best when there was a distinct pustular condition, which was rapidly reduced to simple red spots without heads. In furunculosis the results were truly brilliant, the furuncles disappearing in a few weeks after two or three injections, and no others appearing.

Effect of Floods and Inundations on the Prevalence of Typhoid Fever.

At this season of the year when we see a rise in the number of cases of typhoid fever it seems appropriate to discuss the effect of floods and inundations on its increase. Jacques Bertillon in the *Presse Médicale*, for July 23, 1910, gives the results of a study of the effect of floods in various cities of Europe, notably the great flood of 1910, in Paris. It has been stated in various quarters that the effect of such a flood was to increase the dangers from typhoid fever and other epidemic diseases. The author, on the contrary, finds that the effect of the flood in Paris was not to increase the number of cases or of deaths from typhoid, but rather to decrease them. It would seem that the great washing out of the city streets had rather a cleansing effect than otherwise. A study was made of the occurrence of the fever in the *arrondissements* affected by the flood, and in others to which the flood did not reach, and it was rather higher in the unaffected locations. In the 54 quarters inundated there was a total of 44 deaths from typhoid in 13 weeks before the flood, and only 24 in the same number of weeks afterward. During and after the flood it is probable that the authorities were more careful in disinfection and in isolating cases that occurred than at more healthful times. In ten floods in the city of Dresden, however, typhoid fever was not increased, and the same was true in six floods in Vienna. After the analysis of all these cases it seems evident that the statement made that there is an increase of typhoid after floods is erroneous.

News of the Week.

College of Physicians and Surgeons.—The College of Physicians and Surgeons, Columbia University, New York, opened its 157th annual session on September 28, with a total enrollment of 302 students. The first year class numbers 75. Opening exercises were held on September 29, when Dr. W. G. MacCallum, Professor of Pathology, delivered an address on "The Future of Medicine."

Harvey Society.—The first lecture of the Harvey Society will be given at the Academy of Medicine, New York, on Saturday, October 15, at 8:30 o'clock, by Prof. H. Chiari of the University of Strassburg, whose subject will be "Die Bedeutung der pathologischen Autopsie und sonstiger pathologisch-anatomischer Untersuchungen." In addition to the subjects already published the society announces a lecture by Prof. Jacques Loeb of the Rockefeller Institute for November 19 on "The Prevention of the Toxic Action of Various Agencies through the Prevention of Oxidation in the Cell." Prof. Arthur R. Cushny of the University of London will lecture on January 14 on the "Therapeutics of Digitalis," and Prof. H. Gideon Wells of the University of Chicago on March 25 on "Calcification and Ossification." The lectures are open to the public.

University and Bellevue Medical College.—The opening exercises of the University and Bellevue Hospital Medical College were held in the Carnegie Building on September 28. One hundred and fifty students were registered in the freshmen class.

Cholera in Europe.—The existence of cholera in Naples, which had for some time been suspected, was not officially admitted until September 25. Before that time hundreds of cases and many deaths had been ascribed to "gastroenteritis," and accurate estimations of the real cases of cholera are not possible. In Russia the general situation is thought to be improving, although new cases have been reported in the eastern districts and in parts of Siberia. During the week ending September 30 215 new cases and 80 deaths were reported in St. Petersburg, a considerable decrease from the week preceding. The Russian Sanitary Bureau reported 198,246 cases and 92,329 deaths from the outbreak of the epidemic to the end of September.

Fair for Columbus Hospital.—A festival to raise funds for Columbus Hospital, New York, will be held at the Manhattan Casino on Columbus Day, October 12. The hospital has outgrown its present quarters and funds are needed to erect a ten-story addition containing 300 beds.

Keeping Out Hindus.—The determination that a large proportion of the Hindu immigrants are suffering from hookworm disease may be the means of stopping the influx of these people. The Hindus have been arriving in San Francisco recently at the rate of 300 a month, somewhat to the consternation of the residents of the Pacific Coast.

Charitable Bequests.—The Presbyterian Rest for Consumptives at White Plains, N. Y., receives a bequest of $1,000 in the will of the late Mrs. Laura P. Halstead.

The Nevada State Medical Association held its annual convention at Lake Tahoe on September 19 to 21. The following officers were elected for the ensuing year: *President*, Dr. Sidney K. Morrison, Reno; *Vice-President*, Dr. W. H. Hood, Reno; *Secretary*, Dr. M. A. Robinson, Reno.

The Hyde Park (Massachusetts) Medical Club at its meeting on September 19 elected the following officers: *President*, Dr. Charles Sturtevant; *Vice-Presidents*, Drs. John A. O'Connor and Clarence E. Bryant; *Secretary*, Dr. Arthur E. Grover; *Treasurer*, Dr. Edward H. Baxter; *Director for three years*, Dr. Charles F. Stack.

The Southwest Medical Society will hold its fall meetings at Springfield, Mo., on November 3 and 4. Dr. H. S. Hill of Springfield is the secretary of the society.

The Iowa Health Officers' Association at a recent meeting elected the following officers: *President*, Dr. Fred. Albert, Mason City; *Vice-President*, Dr. Samuel Bailey, Mt. Ayr; *Secretary and Treasurer*, Dr. W. G. Carhart, Marion.

The Knox County (Illinois) Medical Society at its annual meeting on September 22 elected the following officers for the ensuing year: *President*, Dr. D. J. Evans, Galesburg; *Vice-President*, Dr. C. E. Beecher, Gilson; *Secretary*, Dr. G. C. Bower; *Censor*, Dr. J. E. D. Silcox, Rio.

The North Berkshire (Massachusetts) Medical Association at its annual meeting on September 20 elected the following officers: *President*, Dr. William Galvin; *Vice-President*, Dr. L. J. O'Hara; *Secretary and Treasurer*, Dr. L. A. Jones; *Censors*, Drs. O. J. Brown, C. W. Wright, A. K. Boom, and F. H. Howard.

Pike County Medical Association.—The physicians of Pike County, Georgia, have recently formed an association with the following officers: *President*, Dr. J. M. Anderson, Barnesville; *Vice-President*, Dr. W. H. Aycock, Molena; *Secretary*, Dr. M. M. Head, Zebulon.

To Exclude Tuberculous Teachers.—The Board of Education of the city of Camden, N. J., has adopted rules looking toward the exclusion of tuberculous teachers from the public schools and also of tuberculous pupils from the Normal Training School.

Obituary Notes.—Dr. William Frederick Holthausen of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1904, and formerly on the house staff of the Long Island College Hospital; a member of the New York State and Kings County Medical societies, was killed on September 24 when the trolley car in which he was riding collided with another car at Tipton, Ind. Dr. Holthausen, who was thirty years of age, was on his way to Kokomo, Ind., where he was to have been married on the following day.

Dr. G. L. McIntyre of New Martinsville, W. Va., a graduate of the Baltimore Medical College in the class of 1888, a veteran of the Civil War, died in the North Wheeling Hospital on September 12, aged 64 years.

Dr. Wear F. Armstrong of Henderson, Ky., a graduate of the Southwestern Homeopathic Medical College, Louisville, Ky., in 1899, died suddenly on September 12, aged 36 years.

Dr. Emil Wahl of Milwaukee, Wis., a graduate of the University of Leipzig, Germany, in 1884, was accidentally killed while hunting on Muskego Lake on September 9. He was 47 years of age.

Dr. William Cowpe Gardner of New York, a graduate of the Long Island College Hospital in 1892, a member of the New York State and County Medical societies, died at his home of heart disease on September 28, aged 55 years.

Dr. John Erhard of College Point, N. Y., a graduate of the Long Island College Hospital in 1896, died at his home on September 27, aged 48 years.

Dr. John Beverly Crowell of East Orange, N. J. a graduate of the College of Physicians and Surgeons in 1873, died suddenly at his home on September 21, aged 60 years.

Dr. Edward A. Wilcox of Minonk, Ill., a graduate of the Rush Medical College of Chicago in 1857, formerly a member of the State Senate, a member of the Illinois State and Woodford County Medical societies and of the North Central Medical Society, died at his home on September 23, aged 80 years.

Dr. Edwin M. Nelson of St. Louis, Mo., a graduate of the Miami Medical College of Cincinnati in 1874, formerly a lecturer at the St. Louis Medical College and editor of the St. Louis *Courier of Medicine*, one of the founders of the Protestant Hospital and of the St. Louis Training School for Nurses, a member of the American Medical Association and the Missouri State Medical Society, died at his home on September 20 after a long illness, aged 62 years.

Dr. Albini J. W. Dufault of Fall River, Mass., a graduate of the Medical Department of Laval University, Quebec, in 1905, died at his home on September 23, aged 28 years.

Dr. O. N. Dages of Boston, Mass., a graduate of the Harvard Medical School in 1910, and senior house officer in the Boston Floating Hospital, was drowned in Fort Pond, near Littleton, Mass., on September 21, while attempting to rescue a young woman who had gone beyond her depth when bathing. Dr. Dages, who was to have entered the Massachusetts General Hospital in March, 1911, as an interne, was 27 years of age.

Dr. Norman McNab of Montreal, Canada, a graduate of the Medical Department of McGill University in 1907, died of typhoid fever on September 16 at Edmonton, Alberta, aged 24 years.

Dr. Noah Howard Burt of Ocean City, N. J., died at the Hospital of the Universitiy of Pennsylvania at the age of 36 years on September 23. He was graduated from the medical department of the university in the class of 1895.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE COMING SESSION—WAR AGAINST CONSUMPTION, SANATORIUMS, ETC.—INDIAN MORTALITY—LUNACY REPORTS—PTOMAINE POISONING—ITEMS—OBITUARY.

London, September 16, 1910.

The approaching winter session which opens, as usual, at the commencement of October, is the chief subject when students or teachers meet, and even men busy in practice display an interest in an event which takes their memory back to their own student days. If any one were likely to forget it he is pretty sure to be reminded by the receipt of the prospectus for the coming session of his old school, for the deans and others have been busy bringing out these annual pamphlets, and lest any forget, the journals are reprinting the bulk of many, with other information, and so attracting to their pages a large additional number of advertisements. Each brings out its "educational," or "students'" number, the largest of the year, appealing, apparently, to parents who contemplate placing their sons in the profession, and to the sons who have determined to adopt or are inclined to follow the medical career.

The last development of the sanatorium is a group of shelters in which patients can be treated by fresh air and light. Such a group was opened on Monday by the Earl of Warwick as a memorial to the late Alfred Boyd. It is intended for patients of moderate means, and is a gift by Mr. Boyd's widow. The shelters have been designed by Dr. A. E. Lyster. The frame is of wood, and to this is attached canvas of an open texture, part of which can be opened or closed more or less according to wind and weather. Lord Warwick, in his speech, remarked that any poor man might have such a shelter in his own garden, where he could be attended by his own doctor, and cared for by his family and friends. After the opening a conference was held at the County Hall, Chelmsford, when Dr. Lyster explained the system and said there were thirteen unions in the county (Essex), and £1,600 would provide them all with such shelters, while less than

a halfpenny rate per union would cover the cost. Dr. Thresh, M. O. H. for the county, talked cheerily of seeing the way to eradicate the scourge of the white race. Dr. J. E. Squire, of the Association for Prevention of Consumption, was also optimistic, and Sir R. Douglas Powell wrote that after visiting the memorial it seemed to him that Dr. Lyster had provided the best method of dealing with consumption in rural and small urban districts. It was resolved to form an association to promote this method throughout the county, and Lord Warwick agreed to accept the presidency.

The Beninden Sanatorium, in Kent, has received a great addition in the shape of a "postoffice pavilion," erected in the course of a year, and formally presented on Monday by Mr. Samuel, on behalf of 45,000 postoffice members of the National Sanatorium Association. In his speech he declared that year by year the association "gave back life to scores and scores of men and women who felt life slipping away." He even went so far as to say that of all the splendid results of our civilization the finest of all is the "triumph of man over disease." A more reasonable statement of his was that the test of the state of the patients was not at the moment of leaving the institution, but after a sufficient lapse of time to show the durability of the cure. As to this, he said that after two years four-fifths of the patients discharged as arrested were in full work, and of those who had shown signs of improvement one-half were in full work—men and women all of whom would a few years ago have been doomed to speedy death. The National Sanatorium Association originated with societies of postoffice employees, and the subscription to this form of insurance against consumption is only two shillings a year.

At the meeting of the Dublin Hospitals' tuberculosis committee, on the 1st inst., Dr. J. T. Daniel made his report for the last quarter. During the quarter he had visited thirty-one patients at their homes, and forty-one others came to his house to see him. A summary of the two district nurses employed in the work was also submitted and approved, as was that of a nurse working in Teremure. The regulations under the Tuberculosis Act were considered, and a subcommittee was appointed to consider the limitations on notification under the act. The recommendation of the Dublin Hospitals' board that lady almoners should be appointed at all the clinical hospitals was considered and endorsed, these almoners to visit the homes of the out-patients and instruct and advise them concerning sanitary matters, the care of their health, and that of their families, diet, fresh air, exercise, and so on. The almoners are mostly in communication with charitable institutions, through which they can often assist the needy and thereby reinforce the effects of the hospital treatment. The system has been at work more than two years, and the results led the committee to strongly support it.

A Blue Book relating to India was issued last week. It contains a great mass of statistics on various matters; among them some as to the deaths in 1908. The deaths from cholera increased from 103,988, in 1907, to 170,694 in 1908. In the case of plague, there was a great decrease. From fevers a considerable increase, 5,424,372 persons dying in 1908, as compared with 4,464,881 in the previous year. During the last ten years the deaths from fevers have never been less than 4,000,000, but they have never before exceeded 5,000,000.

The Scottish Lunacy Commissioners state in their fifty-second annual report that there has been a fall in the number of pauper patients since the year 1903, which year they think a turning point; so that they anticipate no permanent increase in the number of registered lunatics in the future under present conditions, beyond the rise due to increase of population or such as may occur from mere accumulation through a diminished rate of discharge.

The inspectors for Ireland have issued their fifty-ninth report. There was an increase in 1909 of the same amount as the previous year, but rather less than the decennial average. A table gives the number of all lunatics from 1880 to 1909, which shows an increase in this period of 11,162. The largest increase is in the inmates of district asylums; the pauper lunatics in workhouses have decreased.

The outbreak of cerebrospinal meningitis displays a tendency to spread. Another death has occurred in Nottingham Hospital, and two boys from one of the most crowded districts in that city have been taken to the isolation hospital. Cases have appeared in Essex; one of them died in Chelmsford Hospital, and it is thought others may be fatal.

Further reports of ptomaine poisoning have been received, two from Staffordshire, three from Darlford, and all are attributed to tinned salmon. In one tin cigar leaves were found. A still more startling statement has appeared in some newspapers, to the effect that over 100 cases of ptomaine illness have happened in one of the prisons.

At an inquest on a child who died after the extraction of seven teeth under one anesthetic the jury found that a doctor ought to have been called to administer it.

The Senior Fellow of the Royal College of Surgeons is Mr. Steet, now 92 years of age. He was chief medical adviser at the General Post Office for some twenty years, and retired in 1891. His first diploma is dated 1840. He served on the consulting staff of the Spanish Consulate in London. I am told that at his great age his memory seems good, and his intellectual faculties unimpaired.

Deputy Inspector General John Jack, R. N., died on the 8th inst., at the age of 92. He took L. R. C. S., Edinburgh, in 1839, joined the navy in 1842, became staff surgeon in 1854, fleet surgeon in 1867, deputy inspector general of hospitals and fleets in 1875. He was the holder of the Sir Gilbert Blane gold medal awarded to medical officers for the most approved journals of their practice while in medical charge of a ship of war in the Royal Navy.

Mr. John Langton, Senior V.P., R.C.S., died on the 11th inst., aged 70. He was connected throughout his career with St. Bartholomew's Hospital, of which he was a student, and then passed through the various positions on the surgical side up to the consulting surgeoncy. At the Royal College of Surgeons he became a member in 1861, and fellow in 1865. He has served on the council and court of examiners, and been Hunterian professor, Bradshaw lecturer, etc. He examined in surgery for the Sister College, was consultant to the City Lying-In Hospital, the Trust Society, and other institutions. He edited Holden's "Manual of Dissections," and wrote valuable memoirs on hernia and other surgical subjects in St. Bartholomew's Hospital *Reports*, Heath's "Dictionary of Surgery," Medicochirurgical *Transactions*, etc.

Dr. Lombe Atthill, a former president of the Royal College of Physicians in Ireland, as well as of the Royal Academy of Medicine, died suddenly on Wednesday, at a railway station, after hurrying to

catch a train. He was born in 1827, educated at Dublin University, graduated there M.B., 1847; M.D., 1865. He took L.R.C.S.I. in 1847, and F.R.C.P.I. in 1860. He retired in 1898. He had been Master of the Rotunda, consulting obstetric physician to the Adelaide Hospital, and an examiner on the subject at the Queen's University, and other bodies. His "Lectures on Diseases of Women" reached a seventh edition in 1882. He contributed on his specialty to the *Dublin Quarterly* and other periodicals, and the obstetrical society of which he had been president.

The Influence of Exhaustion Upon Puerperal Morbidity. Based Upon a Study of 5,000 Puerperia. By John T. Williams.
Bacterial Vaccines in Pyogenic Infections of the Urinary Tract. By H. F. Hartwell.
The Place of Tuberculin in the Immunization of Urogenital Tuberculosis. By Geo. P. Sanborn.
Acute Pancreatitis, with the Report of Two Cases. By Philemon E. Truesdale.
The Value of Tuberculin in Tuberculosis of the Urinary Tract. By Hugh Cabot.
Persistent Vomiting of Pregnancy. By F. W. Johnson.

The Influence of Exhaustion upon Puerperal Morbidity.—J. T. Williams bases his paper on a study of 5000 puerperia, and presents the following conclusions: (1) A temperature of 100° F., or above, occurs at some time during the first twelve hours after delivery in about 20.5 per cent. of all cases. (2) The temperature curve during this period in the majority of cases corresponds with the diurnal variation. (3) This elevation of temperature does not necessarily correspond to the duration of labor, but probably does to its severity. (4) The pulse-rate is a less reliable index of exhaustion than the temperature. It most commonly falls during the first twelve hours, a rise in the majority of cases accompanying a corresponding rise of temperature. (5) Puerperal morbidity, with the exception of mastitis, increases in direct proportion to the duration of labor. (6) This increase affects equally all the more common complications of the puerperium. (7) Cases in which there is an elevation of temperature during the first twelve hours after delivery are followed by a higher morbidity than those in which there is not; and when this temperature reaches to 101° or over, the subsequent morbidity is 38.09 per cent. (8) An elevation of pulse at the end of labor is of comparatively slight prognostic importance from this standpoint, but is followed by a slightly increased morbidity. (9) The morbidity is greatest after the high operations, but here, as is also true of the low operations and spontaneous delivery, the morbidity increases in direct proportion to the duration of labor. (10) The morbidity after low forceps is less than after spontaneous delivery, presumably because labor is shortened and exhaustion lessened. (11) From every standpoint from which it has been considered it is evident that exhaustion during labor has a distinct influence toward increasing puerperal morbidity.

Bacterial Vaccines in Pyogenic Infections of the Urinary Tract.—H. F. Hartwell reports his experience in twenty-five cases and gives two histories in detail. He says that the milder cases of bladder infections have responded well to this form of treatment. After the first few inoculations the irritation, frequency, and pain in micturition were lessened and steadily diminished. The condition of the urine showed a corresponding but slower improvement. The bacilluria as in kidney infection was very obstinate. In a few of the bladder cases the urine was obtained free from bacteria after a prolonged treatment, but usually only in conjunction with a urinary antiseptic. In the severe cases of cystitis where there were marked changes in the bladder wall and mucosa, vaccines did not appear to have any effect. In the acute and subacute infections of the kidney pelvis, vaccines seem to offer promising results, but the author regards his number of cases as too small to afford definite conclusions. From his own experience he would say that they are indicated in acute pyelitis which does not respond to ordinary measures. They will probably furnish us with a means of attacking postoperative foci such as an infected ureter stump, which are difficult otherwise to clear up. In cystitis, in a limited number of cases, they offer a less troublesome, possibly a more rapid therapy than that by irrigations and ordinary antiseptics.

The Place of Tuberculin in the Immunization of Urogenital Tuberculosis.—C. P. Sanborn gives the following indications for the use of tuberculin in this class of cases: (1) When we cannot extirpate the organ involved, as the bladder. (2) In organs in which the disease is in an early stage without any considerable disintegration. (3) In case the disease involves both kidneys where it is deemed unwise to operate on either. (4) Postoperatively, in case it is apparent that all tubercular tissue was not removed or where organs affected could not be well extirpated. (5) In any case involving the bladder. (6) In any case in which there is a suspicion that tuberculous tissue has been left behind.

Acute Pancreatitis.—P. H. Truesdale reports two cases, both operated on and recovering.

Value of Tuberculin in Tuberculosis of the Urinary Tract.—H. T. Cabot finds that the remedy has been chiefly valuable in stamping out the secondary processes in the bladder and ureter.

Persistent Vomiting of Pregnancy.—E. W. Johnson reports one case. In one pregnancy all nourishment by mouth was stopped and every two hours a minim of iodine and creosote were dropped on the tongue. In a second pregnancy in the same patient five grains of thyroid extract were given subcutaneously every eight hours. Relief followed in both instances.

Dr. Pohly's Cases of "Anemic Ulcer" of the Throat. By G. Frank Lydston.
Aconite. By John Knott.

Problems of Ambulance Surgery.—Thomas A. Cheatham describes the ambulance system of New York City, and the problems of diagnosis and treatment that present themselves to the ambulance surgeon. Amid the crowded and heterogeneous conditions of the large city there is an ideal field for diagnostic experience, and for coping with problems that embrace every phase of medicine.

Epistaxis in Relation to Constitutional Diseases.—Harold Hays states that the constitutional causes of epistaxis are alterations in the constituents of the blood, disease of the blood vessels, obstruction to the circulation, vicarious discharge, lowered resistance of the tissues due to chemical and bacterial toxins, and pathological infective changes in the nasal mucosa caused by a general disease. The constitutional diseases with which epistaxis is associated are divided into seven groups: Group I, infectious diseases; typhoid fever, etc. Group II, anemias and other blood conditions. Group III, circulatory diseases, including diseases of the heart, liver, kidneys, and blood vessels. Group IV, respiratory diseases. Group V, specific local inflammations, as syphilis, tuberculosis, leprosy, carcinoma. Group VI, miscellaneous diseases: vicarious menstruation, caisson disease. Group VII, drug poisoning: phosphorus, chloralamide, salicylic acid compounds.

Practical Administration of Ether.—Joseph B. Hogan, among other things, emphasizes several points that will do much toward lessening the tendency to or even obviating nausea and vomiting. They are: proper previous diet, thorough bowel elimination, mental preparedness, gradual induction of anesthesia, assisting drainage of the nose and throat by the lateral position of the head, and finally the administration of the minimum amount of ether necessary to attain the desired state of anesthesia.

The Treatment of Peritonitis.—M. F. Goldberger reports the results of the treatment of twenty-nine cases of appendicitis with diffuse peritonitis, with the aid of the Fowler position and the Murphy method of proctolysis. It depended upon "early and direct attack of the infection, minimal disturbance of the surrounding tissues, and intelligent after-care." The abdomen was opened, appendix was located, ligated, and removed, intestinal contents and pus were allowed to flow out and were mopped up with gauze sponges, the gut was handled as little as possible, drainage was instituted and the abdomen was closed around the drains. The patient was kept in the Fowler position from two to six days, and the drains were gradually removed within one week. The Fowler position is the only means by which pus and toxic products in the peritoneal cavity are kept in the pelvis, where the absorptive powers of the peritoneum and lymph glands are much less than at the diaphragmatic region. As soon as the patient is put to bed proctolysis is begun. This is one of the simplest of procedures, and should be continued from one to three days, or until the toxic symptoms disappear, and during this period, in severe cases, the nozzle should never be removed from the rectum. As a cardiac stimulant, camphorated oil, hypodermically, was found of value. Intravenous saline solution, with adrenalin, was the most powerful agent for combating shock before, during, or after operation. Eserine salicylate, 1/64 grain, every four hours, for four doses, following operation, was of value in stimulating the involuntary muscle of the intestine, aiding in the expulsion of gases, and in the prevention of adynamic ileus. For the latter, when vomiting was present, gastric lavage was practised, and carminative enemas with magnesium sulphate were given. For mechanical ileus surgical intervention is the only solution. The cases successfully terminated with no deaths.

The Munich Psychiatric Course of 1909.—Louis Casamajor and Morris J. Karpas describe the postgraduate course of psychiatry established by Professor Kraepelin.

Standardization of Blood Pressure.—Abdullah K. Sallom found that normally the blood pressure does not vary more than about 0.3 millimeters of mercury, and is to be expressed by the following equation: Mm. Hg. $\div$ (W. C. $\times$C.) = P.; in which mm. Hg. represents the height of the column of mercury; W. C. the width of the cuff employed; C. the circumference of the arm, and P. the pressure. The pressure exerted by any fluid depends upon its height and the size of its base. Hence, the area upon which the pressure is exerted plays a most important rôle. If the systolic pressure of a given case is 125 mm. Hg., and if 24 square inches is the total area of the cuff, one square inch will support a column of 5.21 mm. Hg. This is known as the pressure per square inch. Age has been found to have no influence upon this unit pressure. The contradictory statement of other observers has been due to the fact that the circumference of the arm was not taken into consideration. The same is true in regard to sex. Many cases showing differences in the systolic blood pressure as denoted by the height of the column of mercury, nevertheless when standardized gave practically the same ratio for the square inch. The author finds it convenient to express the blood pressure readings as standardized in terms of units. These are obtained by taking the figure or figures before and the first figure after the decimal to represent the number of units. For example, 4.82 mm. Hg. per sq. inch would be spoken of as 48 units. With this unit system it is assured that undreamed of results will be obtained and that the subject will assume an importance equal even to the study of temperature.

Cases of Anemic Ulcer of the Throat.—G. Frank Lydston questions the diagnosis of these cases as reported in a previous number of the journal.

Aconite.—John Knott continues his article on this drug; its place in history, mythology, criminology, botany, therapeutics, and toxicology.

Dislocation of Shoulder Joint Complicated by Fracture, with Report of Two Cases. By John S. McEwan.
A Contribution to Experimental Human Poliomyelitis. By Simon Flexner.
The Arsenical Treatment of Syphilis. By John B. Murphy.

Alopecia and Seborrhea.—C. J. White formulates the lowing conclusions upon a study of 794 cases: (1) Alopecia accompanied by dandruff is the commonest type of loss of hair. (2) Women are more prone to alopecia than men in the proportion of 54 to 46. (3) Possible and principal causal factors of alopecia are hereditary in 30 per cent., dandruff in 79 per cent., systemic depression in 20 per cent., fever in 11 per cent., and maltreatment of the scalp in 50 per cent. (4) Alopecia simplex develops before the age of 30 in 84 per cent. of men, but in only 33 per cent. of women. Dandruff behaves in a similar manner and before the age of 25 attacks 61 per cent. of its future male victims, but only 32 per cent. of its female. (6) Loss of hair in alopecia furfuracea comports itself with these previous two findings, appearing before the age of 25 in 67 per cent. of the men, but in only 34 per cent. of the women. Men are attacked earlier than women with alopecia and seborrhea, but eventually women rather than men fall victims to these conditions. (7) When dandruff is present it is apt to be abundant rather than slight, oily rather than dry, and to be accompanied by itching. (8) Drugs most successful in the treatment of dandruff and loss of hair are bichloride of mercury, tannic acid, and chloral hydrate. (9) From a temporary view while therapeutic results are disheartening, a good response follows in 48 per cent. of men and 56 per cent. of women. Seborrhea simplex is a disease of childhood or early adult life, developing before the age of 30 in 71 per cent. of men and 96 per cent. of women. Other seborrheas of the skin, such as acne vulgaris, acne rosacea, eczema seborrheicum and Fordyce's disease, may accompany loss of hair and dandruff. (10) Dyspepsia, on the other hand, exists in a surprisingly small percentage of these cases. Seborrhea simplex is a truer form of dandruff than that accompanying loss of hair. (11) In alopecia areata dandruff is a frequent accompaniment, and we also find one attack of the disease apt to be followed by one or more later outbreaks. (12) In alopecia areata and in ringworm of the scalp the region most affected is the occipital.

Study of the Bacterial Flora of the Nasal Mucosa in the Presence of Rhinitis.—W. Walter has investigated 250 cases. He says that the evidence seems indicative that the diphtheroids, particularly the *Bacillus segmentosus* of

Cautley are concerned in the production of common cold in its typical manifestation in the nose, and that there is much evidence that it occurs in epidemic form. The *M. catarrhalis* is much more general in its manifestation, and probably more severe in its effects, while the symbiosis of the two increases the virulence. The pneumobacillus of Friedlaender is much more concerned in chronic conditions and is probably identical with the ozena bacillus. The pneumococcus of Fraenkel flourishes in any part of the respiratory tract, and when virulent has been found in pure culture. Clinically the segmentosus is most likely to be in the nose, but may cause otitis media; *M. catarrhalis* is most apt to invade the larynx and trachea, but may occur in the ear or nose with variable frequency. The pneumobacillus is mostly confined to the nose and sinuses. Pyogenic cocci are non-pathogenic locally except as secondary invaders. The bacterial flora of the nose in America does not materially differ from that of other countries, but the ratio of finding must be largely governed by environment, occupation, social position, etc.

Choked Disc in Relation to Cerebral Tumor and Trephining.—A. Saenger discusses theories of choked disc and reviews the literature of the subject with the theories of various authors and summarizes nineteen personal cases. In two of these choked disc decreased only after the trephining hole had been enlarged, allowing a great outflow of cerebrospinal fluid. In two cases decompression had no effect whatever so far as the choked disc was concerned. These were cases of extraordinarily large-sized, rapidly increasing brain tumors. In only one case, a tumor of the base, the operation was followed by high fever and speedy death. In all the rest the effect of decompression on choked disc was obvious. By decompression the author implies not merely trephining, but removal of the dura. In all the author reports 26 cases of decompression. Seven were tumors of the cerebellum, three were cases of tumors of the acoustic nerve, one, a tumor of the parietal lobe, the patient living for nine months, three were tumors of the frontal lobe, three tumors of the base. In the latter decompression was of no avail. Five cases are referred to, all presenting symptoms of a brain tumor, choked disc, headache, vomiting, etc. When decompression was performed there was no tumor found. All the patients recovered and are now leading active lives.

A Case of Diffuse Purulent Ventriculo-Septal Myocarditis with Adams-Stokes' Syndrome.—H. G. Beck and W. R. Stokes report this case of diffuse suppurative myocarditis. Clinical history indicates that the patient had been suffering from syncopal attacks for seven months. It is difficult to account for the earlier attacks unless it can be believed that there were recurrent purulent infiltrations of the bundle of His with damage to the muscular fibers. There was found on autopsy an acute primary purulent infiltration involving the bundle of His.

A Study of a Case of Heart Block.—See MEDICAL RECORD, Vol. 77, page 1029.

Instruction of the Public in Antituberculosis Measures by a Traveling Car Exhibit.—George Homan gives a description of a car used in Missouri with an account of its tour throughout the State. At different points there was hearty cooperation with the local authorities, societies, etc.

External Preparations of the U. S. P. and the National Formulary.—S. N. Hallberg discusses various preparations of the U. S. Pharmacopœia and National Formulary.

Medico-Pharmaceutical Ethics.—A. S. Musante speaks of drugstore prescribing, substitution, crude dispensing, etc.

New Test for Cancer of the Stomach with Suggested Improvements.—Description of the tryptophan test, by J. W. Weinstein. A serious obstacle in the way of its employment reliably is the fact that free hydrochloric acid interferes with the activity of the cancer enzyme, or may destroy it altogether.

Clinical Study of a Case of Pseudoleukemic Anemia of Infancy.—T. J. Elterich reports the carefully prepared history of one case with autopsy findings.

Dislocation of Shoulder Joint Complicated by Fracture.—J. S. McEwan reports two cases of this complication, in one of which he operated. The success in this case leads him to advise operation in all similar cases.

The Contribution of Experimental to Human Poliomyelitis.—S. Flexner states that the experimental study of poliomyelitis has yielded a large number of important facts relating to the disease occurring through infection in man. He is inclined to the belief that there may be several varieties of poliomyelitis, but that the epidemic form, like the epidemic form of meningitis, may be distinguished from the rest by being invariably the product of a specific microorganism.

The Arsenical Treatment of Syphilis.—J. B. Murphy reports a case of chancre derived from a common drinking cup, which case showed marked improvement after a two weeks' treatment with sodium cacodylate.

Vaccine Therapy: Its Administration, Value and Limitations. By Sir Almroth E. Wright.
A Case of Chondrocarcinoma of the Testis. By William Sheen, H. A. Scholberg and R. L. Mackenzie Wallis.
The Enucleation of Tonsils with the Guillotine. By Samuel S. Whillis and Frederick C. Pybus.
Verminous Appendicitis. By H. A. Lediard.
A Note on the Toxicology of Carbon Monoxide. By W. James Wilson.
The Ventilation of Ships, Particularly Merchant Ships. By Fleet-Surgeon W. E. Home.
The Pioneer in the Hygiene of Ventilation. By David Fraser Harris.
The Benenden Sanatorium and Industrial Insurance for the Treatment of Phthisis. By T. D. Lister and W. D. Wilkins.

Vaccine Therapy.—Sir Almroth E. Wright discusses the administration, value, and limitations of this new therapeutic measure, whose fundamental principle is to exploit in the interest of the infected tissues the unexercised immunizing capacities of the uninfected tissues. As regards its clinical limitations, these are not so narrow as have been contended. Vaccine therapy promises to be brilliantly successful in pneumonia; it holds out promise in typhoid fever and in many forms of rheumatism; it supplies the only ray of hope in endocarditis; inoculation or a system of regulated autoinoculation is the only standby in phthisis; it has already proved its superiority over operative procedures in tuberculous glands and many other forms of tuberculous infection; it has also given very favorable results in diseases of the mouth, nose, ear, and genitourinary system. Extensive tuberculous ulcers have healed up under vaccine therapy without the formation of scar tissue. *x*-ray dermatitis, with extensive streptococcus infection, inflammatory trouble at the roots of the teeth, and pruritus ani have all responded favorably to the use of vaccine. It is probable, also, that these may yet be of value in hay fever, urinary calculus, indigestion, vomiting, and flatulent distention of the stomach, epilepsy, cancer, diabetes, and enuresis. As regards the bacteriological limitations, it is noted that a complete and exact diagnosis is a necessary preliminary to a successful application of vaccine therapy. The risk of accepting an incomplete for a complete diagnosis is most conspicuous in connection with syphilitic and tuberculous infections. In cases of long-standing infections repeated inoculations are necessary. The measurement of the opsonic power of the blood is a partial evaluation of the antibacterial defences of the body; it increases and diminishes in correlation with the patient's clinical condition. In ordinary cases of localized streptococcus, or staphylococcus infection, it is not necessary to measure

the opsonic index, for in these cases the appropriate doses of vaccine are known, and the clinical symptoms furnish a sufficient guide. This is also true of acne and croupous pneumonia. In dealing with a case of staphylococcus infection, such as sycosis, which has obtained a firm hold upon the patient, it is often necessary to regulate the dose by means of estimations of the opsonic index. This holds true of the chronic streptococcus infections associated with tuberculous diseases of bone, and of the chronic coliform infections.

Chondrocarcinoma of the Testis.—William Sheen, H. A. Scholberg, and R. L. Mackenzie Wallis report a rare case of this growth, belonging to the class "embryoma."

Enucleation of Tonsils with the Guillotine.—Samuel S. Whillis and Frederick C. Pybus state that the importance of total removal of diseased tonsils is not sufficiently recognized. By a special method of using the Lennox Brown modification of the McKenzie guillotine, they were able in nearly fifty per cent. of all cases, including tonsils of all shapes and sizes, to enucleate the tonsil complete in its capsule in one piece. The anatomical condition of the tonsillar lacunæ makes them readily retain any infected material, and they have been found to contain most pathogenic organisms. In a fair proportion of cases the tonsil is not enlarged, but is considerably diseased, and the doctrine of septicity, not size, is an important one. Frequently the most septic cases are those in which there may be a considerable mass embedded in the pharyngeal wall, while there is seen only a small slit between the faucial pillars. The baneful effects of tonsillar infection are numerous, as follows: Recurrent sore throats, peritonsillar abscess due to infection through the bases of the lacunæ, foul breath, and bad tastes in the mouth, tuberculosis of the cervical glands originating from infection through the tonsil, acute and chronic rheumatism resulting from streptococcic infection, and a small septic tonsil may be the cause of a general ill-health, and often the undiscovered focus of some distant infection. The advantages of tonsillar enucleation by means of the guillotine are that the method is simple, rapid (the total time required to do ten cases being forty minutes), it can be performed under ethyl chloride anesthesia, is applicable to tonsils of all shapes and sizes, the whole operation is under direct vision, and the pressure exerted by the finger and by the guillotine can be regulated to a nicety.

Verminous Appendicitis.—H. A. Lediard reports a case of appendicitis in a child in which the appendix after removal was found to contain a nest of actively moving threadworms.

Toxicology of Carbon Monoxide.—W. James Wilson comments upon the increased toxicity of water-gas as compared with coal-gas.

British Medical Journal,

September 17, 1910.

Remarks on Eighteen Cases of Spinal Analgesia by the Stovaine-Strychnine Method of Jonnesco, Including Six Cases of High Dorsal Puncture. By Lawrie McGavin.
Remarks on Anesthetizing Patients for Operations on the Throat, Nose and Accessory Sinuses. By Stuart V. Stock.
State Insurance and the Poor Law Commission. By J. H. Keay.
State Invalidity and Sick Insurance. By E. Rowland Fothergill.

Spinal Analgesia by the Stovaine-Strychnine Method of Jonnesco.—Lawrie McGavin, in reporting the results of the use of this method in eighteen cases states that Jonnesco's method is based on the supposition that the addition of neutral strychnine sulphate to the stovaine employed is capable of overcoming the danger of respiratory paralysis when the injection is made between the spines of the first and second dorsal vertebræ, or when, the solution having been injected at a lower level, it has been purposely allowed to gravitate to the upper regions of the cord, the patient being in the Trendelenberg position He states that he has not been convinced of the safety of Jonnesco's method; that it has not borne out the contention that the addition of strychnine is capable of preventing respiratory paralysis. Although the latter occurs in some cases, in others there is no sign of it. The method appears to be fraught with considerable danger. Four successful cases of high puncture serve, so far as analgesia above the phrenics is concerned, to show that the method has, at least, some element of possibility in it; it is, however, uncertain, imperfect at present, and of doubtful value in replacing general anesthesia. The cases of low puncture serve to show little else than that strychnine can be injected into the spinal canal without producing spastic symptoms, and that it undoubtedly results in a shortening of the period of analgesia usually resulting from the use of stovaine alone. The effects of the analgesia on the cranial nerves appear to be irregular. The first, second, third, and fourth nerves remain unaffected; the fifth and seventh are at times under control; the sixth, eighth, ninth, tenth, and twelfth are unaffected, while the eleventh may or may not be paralyzed. Stovaine is not a cardiac depressant, although it is to some extent a vasodilator. The author can see no object in adding strychnine to cases of low spinal analgesia, since no difficulty has been found without its use even when such analgesia has been pushed to the level of the clavicles. This height is not to be aimed at. The author prefers the stovaine-glucose method of Barker, by means of which 500 operations have been performed in the Seamen's Hospital with entire satisfaction.

Anesthesia for Operations on the Throat, Nose, and Accessory Sinuses.—Stuart V. Stock describes his routine method of inducing anesthesia with ethyl chloride and ether, and then, after a varying time, of substituting the two-bottle method—namely, a plain domette-covered mask (Murray's) and two drop bottles, one containing chloroform, the other ether. These two anesthetics are added to the mask in such quantities and at such intervals as may be thought necessary, the smallest possible amount of chloroform being used, and at times altogether omitted, resulting in a pure open ether administration. The method is superior to using a definite mixture of the two drugs, as the proportions can be so easily varied to suit individual cases.

State Insurance and the Poor Law Commission.—J. H. Keay states that State insurance would provide an adequate remedy for a great deal of poverty and pauperism due to inadequate medical attendance. He discusses this subject in relation to private practice, to voluntary insurance by means of clubs, friendly societies, and provident dispensaries, to charity through the medium of hospitals and medical missions, and describes a system of compulsory insurance.

State Invalidity and Sick Insurance.—E. Rowland Fothergill states that the physical deterioration resulting from unemployment, insufficient or bad food and housing, and neglected ailments, with all the consequent injury to succeeding generations, require that the State recognize their existence and urgency, and should take steps to stop this human wastage. The scheme should be worked on an insurance basis, and the State would guarantee to the beneficiaries medical attendance during accident and illness, sick pay during accident and illness, pensions when permanently out of work through illness before being seventy years of age, sustenance and medical attendance for the families of those laid by, and adequate wages during unemployment due to no cause over which the beneficiary had a control, or which is a result of physical defects. In addition, the State would guarantee to trade unions, friendly societies, State hospitals and dispensaries, nursing and convalescent homes, nursing associations, and all branches of the medical profession, adequate funds wherewith to meet the claims on their respective services.

Berliner klinische Wochenschrift,

September 5, 1910.

Early Symptoms of Tetanus (continued from last number).—Evler continues the description of the prodromes and early symptoms of tetanus traumaticus, which well illustrate the subtle and multiform nature of the symptoms before trismus sets in. Precardial anxiety and oppression are doubtless of medullary origin, and are seen in other intoxications. A not uncommon early symptom is cough of a spasmodic type which closely simulates pertussis. Epileptiform convulsions may accompany trismus. Contrary to certain teachings, there may be little or no fever in the early stages. The pulse varies greatly—may be slow or rapid by turns. Dicrotism or skipping a pulse-beat may be present. As already stated, the pulse is stronger in an affected limb. Trismus is preceded by paroxysms of yawning; the jaws may "snap" in this act and may even be subluxated. These acts of yawning are accompanied by pains in the temporal and masseter muscles. Nose-bleed is common. Some cases suggest a toxemia; others rather a simple anemia. Sometimes the cheeks are flushed, at others pale, with pallid lips. The expression in general changes, the patient looking woebegone. The particular expression sometimes seen and due to spasm of the "smiling" muscles—commonly known as *risus sardonicus*—is well enough known to readers. Hyperacusis occurs, resembling that produced by non-toxic doses of strychnia. This is usually followed by auditory hallucinations and deafness—due perhaps to spasm in the tensor tympani and stapedius muscles. Of special interest is the sudden blanching of individual hairs or hair tufts. Stiffness of the limbs, with rheumatoid pains, is a common symptom. With these in an undoubted hypersensitiveness to cold and a resulting tendency for artificial heat in all forms. There is weakness in the total musculature and an intentions-tremor in all common acts like shaving. These weaknesses may be accompanied at times by violent spasmodic acts. Thus a patient who can hardly protrude his tongue may have it bitten by a spasm of the chewing muscles. Increased perspiration is an early and constant symptom, the sweat possessing, from old records to the present, all kinds of disagreeable properties. Speech disturbances are common and variable. So many nervous symptoms occur that tetanus, it would seem, should be placed under the neuroses, as has often been done. If tetanus be not a traumatic neurosis, then there is no such category of disease—judged clinically, of course. The same is true of rabies humana, and both conditions may exist on a purely neurotic basis. The author devotes much space to diagnosis, in which a score of diseases may require differentiation; likewise to the early treatment largely in the prodromic stage and with special reference to serotherapy.

Vaccine Treatment of Gonorrheal Complications.—Reiter and Friedlander have passed on this subject, which is of exclusively British origin, in a favorable, albeit critical, fashion. Reiter, taking the theoretic end, deduces from Wright's original postulates the following principles of treatment: (1) Affections localized and not severe may be selected by serological methods and treated with complete serological control. (2) In markedly localized disease small immunizing doses must be first used; then, after three to five days, medium doses should be used on an increasing scale. The increase should not be extended too far, and after a maximum is reached no injection should be given for a week or ten days, after which it may be resumed at the leaving-off dose. Exceptions in which higher quantities are given are furnished only in exceptional cases—as when gonorrheal furuncles threaten to break through the skin. The practical end, handled by Friedlander, comes out as follows: Epididymitis in all stages—twenty-five cases—was treated beneficially in a majority of cases. Reading between the lines we must conclude that the resource proved very satisfactory. In a small series of cases of acute prostatitis there was no evidence that the treatment made good. The remaining material, comprising gonorrhea of the adnexa of both sexes, did not show, by reason perhaps of the small number of cases, that the vaccine treatment offered any advantage. Friedlander sums up as follows: There were unusually good results in both acute and subacute gonorrheal prostatitis. In all other complications the results were dubious. He would, in fact, continue to employ the silver treatment in some of its manifold phases.

Wassermann's Reaction with "606."—Lange, assistant to Wechselmann, sums up his experience as follows: He has now treated 268 cases with "606," which have been submitted to Wassermann's test at various times. It is apparently assumed that all these cases gave at the outset a positive Wassermann. But after four or five weeks positive cases were limited to 153. Further study of the article shows that eighteen of the original cases untreated gave a negative reaction, although these comprised one case of syphilis maligna and one of early tabes. This leaves sixteen cases, and of these nine had gone through thorough mercurial treatment. There were two cases of clinical chancre which gave a negative Wassermann and no results from "606." So the remaining cases may be reasoned away in such manner as to throw doubt on our ability to recognize or treat syphilis according to rule. In this series many of the subjects were practically predoomed to death by the heart, lungs, arteries, kidneys, etc. To drag in an allied factor in such miscellaneous material would seem unfair. All this participation of syphilis in lethal or dangerous affections must needs be eliminated in considering individual series.

Münchener medizinische Wochenschrift,

September 6, 1910.

A Procedure for Nitrous Oxide-Oxygen Anesthesia.—Neu, as a result of animal experiment plus clinical experience, believes that an extreme combination of anesthetics may lead to a desired result. Thus in a given case he combines morphine, scopolamin, introus oxide and oxygen, thereby acquiring an ideal narcosis, with no deleterious effects on the heart and lungs, and without unpleasant sequelæ of any sort.

On the Action of "606" on Psoriasis and Lichen Ruber.—Schwabe, after relating several cases, states that the action of 606 upon these two diseases is of especial interest. It has been assumed that these two affections are of spirillic origin, so that a spirillotropic substance like 606 might naturally attack them. Despite theory, however, numerous cases of these chronic skin diseases have actually yielded to the 606 remedy. It is, however, possible that psoriasis and lichen may be actually due to a specific neurodermatitis which comes readily under the domain of an antisyphilitic remedy. At present the skin conditions may be due either primarily or secondarily to the exciting cause.

Amyloidosis in Japan.—Tanaka notes the relative infrequency of general amyloid disease in Japan. This refers naturally to the clinical expression of the disease. A microscopic study of the viscera of miscellaneous cadavers, especially those dead from tuberculosis, syphilis, cancer, shows abundant evidence of amyloidosis. It affects, however, local tissues, and is demonstrable by special chemical reactions. Thus we may find foci of amyloidosis in a kidney without functional anomalies; or we may find the same as part of a picture of chronic nephritis. The same is true of other tissues which tend to show amyloidosis. According to the degree or quality present, the amyloid

element may be regarded as actively pathogenic or only accidentally present. The author believes that amyloid tissue is no other than a combination of nitrogenous albumins with chondroitin sulphuric acid. That amyloidosis cuts no greater figure in the visceral pathology of the Japanese is explained by the vegetarian or N-poor diet of the average Japanese.

Gonorrheal Peritonitis in Man.—Bodenstein refers naturally to the paucity of cases of peritoneal gonorrhea in man as compared with the frequent incidence of this sort in women. Without going beyond the details in a particular instance, the author cites an illustrative case. Youth aged 22, with typical urethral discharge. Treated with a silver salt and urotropin. About two weeks after diagnosis patient showed a decided inflammatory reaction, and was operated on for appendicitis. Nothing found in the ordinary expectation, but evidences of serositis. The old experience that peritonitis may result from spermatocystitis is only emphasized in that connection.

Deutsche medizinische Wochenschrift,

September 8, 1910.

Toxemia of Pregnancy.—Hofbauer reviews to date our knowledge of this condition or, better, of these conditions. The development of the fetus and its envelopes has a certain reaction upon the mother which under definite conditions assumes the picture of a severe autointoxication. It no longer appears likely that the toxemia is due to the failure of the mother to produce antibodies to neutralize the supposedly foreign albumins of the fetus, placenta, etc. The evidence to-day accuses certain enzymes formed in the placenta, concerning which we know but little. Even in normal pregnancy degenerative processes in the liver and kidney may be demonstrated, the result of fetal influences. At the same time we find a hyperplasia of the glands which possess an internal secretion, such as the thyroid. With such associated changes practically constant, and indicative of metabolic anomalies, it is not difficult to understand that these normal anomalies may pass readily into definite toxicoses, manifested in one case by eclampsia, in another by pernicious vomiting. Thus far our knowledge of these conditions is histological and biochemical, etc. We have not attained further to a knowledge of the pathogenesis of these autointoxications.

Bronze-Diabetes.—Ridder does not seem to have advanced our knowledge of this obscure affection. His paper consists of the relation of a case, with a recapitulation of the views of authorities. His own case may be summed up as follows: Four years before the death of a certain patient there appeared pigmentation of the extremities, with slight edema over the tibiæ. There was evidently no diagnosis made at the time. One year later enlarged liver was made out, with diagnosis of "hypertrophic cirrhosis of the liver" with cutaneous pigmentation. At this period there was no diabetes, alimentary glycosuria, or carbohydrate intolerance. But six months before death the picture became one of typical bronze-diabetes. This case admittedly throws no light on the latter affection, cases of which tend to exist *sui generis*. In the author's, as in many other cases, it is impossible to establish a consequential relationship between suppositious causal factors and the disease itself. There are elements which are known to set up disease, but not the disease in question. The only constant element is the injury of the liver parenchyma by some unknown noxa, which betrays its presence by pigmentary changes, yet which cannot be recognized anatomically. The injury to the liver parenchyma is shown by the accumulation of the products of blood decomposition in that gland and eventually in other glands. These offending substances finally set up pancreatic glycosuria.

Influence of Momburg's Method on the Heart and Circulation.—Tornai, in discussing Momburg's aorta compression warns against its too free use in diagnostic procedures. The recent tendency has been to employ it as a test of the circulation. He would never employ it in heart disease, arteriosclerosis, nephritis, Basedow's disease, or even in simple plethora. Any patient with one of these diseases may die on the table as a result of aortic compression. It is cold comfort to assert that no blood was lost in the trial. The author appears to deal throughout with abdominal compression with a rubber tube. In some cases, at least, powerful heart stimulants were freely used during the experiments.

Clinical Value of the Pinoff Levulose Test for Sugar in the Urine.—Fleischer and Takeda deal wholly with the Pinoff test for levulose as advanced in 1905. They conclude that its value for the recognition of levulose in the urine is useful only under certain conditions. In comparison with the Selivanoff reaction it may be said that both are certain, yet both may fail.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

L'AEROPHAGIE. Par le Dr. H. MAUBAN. 12mo; paper; 160 pages; illustrated; 2 fr. 50. G. Steinheil, Paris, France.

PRAKTISCHE WINKE FÜR DIE CHLORARME ERNÄHRUNG. Von Prof. Dr. H. STRAUSS. 8vo; paper; 37 pages; M., 1.00. S. Karger, Berlin, Germany.

Book Reviews.

Dislocations and Joint Fractures. By Frederic J. Cotton, A.M., M.D., First Assistant Surgeon to the Boston City Hospital: Assistant Professor of Clinical Surgery in Tufts College Medical School, Boston. With 1201 illustrations, 830 from drawings by the author. Philadelphia and London: W. B. Saunders Co., 1910.

This appearance of a work fully covering the subject of dislocations and joint fractures is justified by the vast progress that has been made within recent years in the diagnosis and treatment of these conditions, which progress may be attributed largely to the employment of the *x*-rays as an accessory method of diagnosis. Moreover, to quote the author, "injuries to and about joints constitute one of the most doubtful fields of surgery, a field strewn with wrecks,—the products of mistakes and of unavoidable difficulties, prolific in discontent and in resultant actions at law—actions based only too often on unavoidable uncertainty or error." The value of a work of this kind to the general practitioner is obvious, for he is called upon, and should be able, to treat most fractures and dislocations. The author discusses the common types of fracture and luxation, their diagnosis and characteristic *x*-ray appearances, and describes with the aid of numerous illustrations the methods of reduction and the application of apparatus. The common failures in reduction and the expected complications are carefully detailed, together with the methods of their detection and remedy. After-treatment and prognosis are also fully covered. One of the many admirable features of this book is the fact that of the 1201 illustrations more than two-thirds are from original drawings by the author, whose artistic skill enabled him to make the illustrations integrally a part of the text.

Théorie Physico-Chimique de la Vie, et Générations Spontanées. Par Stéphane Leduc, Professor à l'École de Médecine de Nantes. Paris: A. Poinat, 1910.

In the non-technical language suitable for the general reader the author presents the results of his investigations into the artificial production of life, and an elaborate theory of its chemicophysical origin. He shows how it is possible, by means of the diffusion of liquids, to obtain structures similar to cellular tissues, for example, striated structures indistinguishable from the microscopic appearance of striated muscle, and polypoid forms identical in appearance with those belonging to the lower orders of life. Moreover, by the same process, he is able to reproduce the complicated movements observed in cells during the process of karyokinesis. The subject matter of his thesis is comprised under the separate headings of life and living beings, solutions, electrolytic solutions, colloids, diffusion, and osmosis, periodicity, cohesion, and crystallization, karyokinesis, energy, synthetic biology, osmotic growth and morphogenesis, osmotic phenomena of life and physiogenesis, and evolution and spontaneous generation.

Mammalian Anatomy, with Special Reference to the Cat. By Alvin Davison, Ph.D., Ex-Fellow of Princeton University: Professor of Biology in Lafayette College. Philadelphia: P. Blakiston's Son & Co., 1910.

The issuance of a second edition of this manual is evidence of the growing demand of a knowledge of mammalian anatomy as one of the first requisites for entering upon an intelligent study of medicine, as well as for students of modern psychology, the teachers of physiology in high schools, and the directors of gymnasiums.

The Expectation of Life of the Consumptive After Sanatorium Treatment. By Noel Dean Bardswell, M.D., M.R.C.P., F.R.S. (Ed.), Medical Superintendent, King Edward VII Sanatorium, Edinburgh, Glasgow, and London: Henry Frowde and Hodder & Stoughton, 1910.

The criterion of the value of any method of treatment of a chronic disease must be the ultimate results attained. This is especially so in the case of a disease which, like tuberculosis, tends to repeated relapse even after long periods of quiescence. It is only recently that any systematic investigation of the subsequent histories of patients discharged from sanatoria has been published. This has been done at the Adirondack Cottage Sanitarium and is especially valuable—first, because of the long period (twenty-five years) which the investigation covers, and, second, because of the thorough and satisfactory method of the investigation. The present author, while dealing with a much smaller number of cases, has, nevertheless, followed a similar method in his work which accordingly makes a comparison of results the more valuable.

The present work is an inquiry into the subsequent histories of 241 cases discharged from sanatoria from 1901 to 1905 inclusive, according to the method adopted by Brown in the Adirondack Cottage Sanitarium, using a practically identical nomenclature as to classification. As might be expected, the inquiry shows the superior advantage of treatment during the "incipient" stage of the disease. Nevertheless, it is encouraging and not a little gratifying to note the comparative longevity among the "Moderately Advanced" cases discharged "Improved" or "Arrested."

Roughly speaking, the author has found that approximately 50 per cent. of all patients, representing all stages of the disease upon their admission to sanatoria, are found to survive at the end of from five to eight years subsequent to their discharge. Much detailed information is given as to social condition and occupation following sanatorium treatment and a considerable part of the volume is given over to individual histories of the 241 cases. The work is a valuable addition to our statistics on tuberculosis.

A Textbook of Experimental Physiology. For Students of Medicine. By N. H. Alcock, M.D., D.Sc., and F. O'B. Ellison, M.D., St. Mary's Hospital Medical School, University of London. With a preface by E. H. Starling, Jodrell Professor of Physiology in the University of London. Philadelphia: P. Blakiston's Son & Co., 1909.

This work is aimed to put into practice the syllabus of practical physiology as prescribed by the University of London, and to furnish the medical student with such essentials in experimental physiology as will assist him in the comprehension and treatment of diseases. According to Professor Starling the medical student "should have a mental image of the organs of the animal body, that the latter becomes, so to speak, transparent, and he is able mentally to picture the disorders of function, which he infers from the signs and symptoms utilised by the medical man for the purposes of diagnosis."

A Short Handbook of Cosmetics. By Dr. Max Joseph, Berlin. Third Edition, with 151 Recipes. Authorized English Translation. New York: E. B. Treat & Co., 1910.

As the author states in his preface, the subject of cosmetics has been too long neglected by physicians. In recent years the importance of the knowledge of this department of dermatology is being realized more and more among practitioners. This small volume treats in a satisfactory way of cosmetics of the skin, hair, nails, and mouth. There is a good index.

The Family Health. By Myer Solis-Cohen, M.D., Fellow of the College of Physicians of Philadelphia. Philadelphia: The Penn Publishing Company, 1910.

Although it is said that "he who doctors himself has a fool for a patient," nevertheless there is a wide field for just such a book as Dr. Solis-Cohen has written for laymen. The subject matter is presented in popular form and includes the consideration of personal hygiene, problems of public health, care of infants, management of the sick, domestic medicine, and emergencies. The style is simple and clear, although scientific reasons are given for the measures advised. The table of contents is given in considerable detail, but there is no index.

The Practitioner's Case Book: For Recording and Preserving Clinical Histories. Prepared and Arranged by the Editorial Staff of the Interstate Medical Journal. Imperial octavo; 286 pages; full cloth binding. Printed on bond writing-paper. With 80 colored anatomical charts (detachable), showing outlines of body and skeleton in light red and the viscera in pale blue. Index for listing patients both by name and case number. St. Louis: Interstate Medical Journal Co., 1910.

The above title gives a sufficiently clear idea of the nature of this volume. Two pages facing each other are allotted to the history of each patient, ample space being provided for notes of physical examination and of subsequent developments of the case. The detachable charts facilitate very much the recording of the findings. Of course no cut-and-dried *schema* can ever fit all cases, yet the forms contained in this book should prove very useful to beginning practitioners in helping them to keep an orderly account of their clinical material. The volume is recommended to such physicians as have not succumbed to the allurements of the more modern separate card system of keeping their notes.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held May 17, 1910.

DR. C. N. B. CAMAC IN THE CHAIR.

THIS meeting was occupied by reports from the medical departments and laboratories of the Presbyterian Hospital.

A Simple Method of Enumerating Vaccines.—Drs. R. L. HUTTON and F. DU BOIS presented this communication. No one knew when giving vaccines how many organisms he was giving, and this was because of the large percentage of error in the most careful enumeration of the vaccine. They had found that the most careful work with the Wright method of enumeration gave results which varied from 19 to 66 per cent. In their own series thus far with this method the average variation had been 35 per cent. The method of enumeration used by Emery, that was, by means of the blood pipette and counting chamber, such as was used for counting red blood cells, was very much more accurate. In no case had the percentage of variation been higher than 20 per cent. and the average variation was 10 per cent. Both of these methods took considerable time and were fatiguing to the eyes. In seeking a method which would give more accurate results than Wright's and at the same time eliminate the necessity of using the microscope, they had been led to experiment with the method used by Gabritchensky. This consisted in centrifuging the emulsion and determining the number of organisms of a given kind contained in a given volume of the sediment. In the preparation of vaccines from streptococcus obtained by blood culture and from staphylococcus aureus the method had given them very satisfactory results. When compared with their most accurate determinations by microscope, the variation averaged about 15 per cent. In no case was there a variation of more than 31 per cent. and variations of 1, 4, 5, and 3 per cent. were noted in certain cases. Consequently they felt that this method was more accurate than Wright's, nearly as accurate as the blood pipette, and was more rapid and saving to the eyes of the bacteriologist than either. The method was as follows: After the emulsion had been collected in the capsule, filtered, shaken thoroughly, and heated, it was pured into a specially made glass centrifuging tube, the lower portion of which was accurately graduated to read in hundredths of a centimeter up to 15. The tube was then placed in a centrifuge capable of about 3000 revolutions per minute and centrifuged for ten minutes at top speed, or until the supernatant fluid became clear, and the volume of sediment had remained unchanged during the last five minutes of centrifugalization. The amount of sediment was then read off in terms of one hundredth centimeter, and upon this the number of organisms in the whole amount of vaccine was calculated. Their reason for making this report public so soon, before a much larger series had been studied, was to call the attention of those who were preparing vaccines to a method which would save them time and work was to call the attention of those who were preparing vac- with the microscope without any loss of accuracy in results. As the number of cases tested in this way increased the factors would no doubt be subject to slight change, but the results would be much less variable than those obtained by Wright.

An Apparatus for the Collection of the Excreta of Infants.—Dr. EUGENE F. DUBOIS exhibited this apparatus. He said that in the study of infant feeding it was of the utmost importance to be able to make accurate analyses of urine and feces. In most of the devices in use for this purpose the child's body was supported on pillows and the buttocks were hung over a dish to catch the feces. The legs were tied to canvas strips which were tied to the sides of the crib or to a bar above the crib. The apparatus which Dr. DuBois showed was very compact and did not need to be tied to the crib. The child lay on the mattress with the buttocks in a trough which immobilized the pelvis and kept the anus over the receptacle for the feces. The thighs were held firmly against the slanting part of the mattress by means of cloth bands. This was the only restraint necessary, though he usually pinned one band over the lower part of the abdomen. The urine was collected by the device used by Dr. Howland, a test tube made to fit the penis and held securely in place by means of a girdle. The tube led to a flask, which should be a large one, as a seven months' old baby could sometimes void a third of his own weight of urine in twenty-four hours. The receptacle which Dr. DuBois had used for collecting the feces was a sugar scoop with the handle sawed off. The apparatus had the disadvantage of being rather hard to make. Its advantages, however, were that it was compact, fitted easily in a bassinette, could be moved outdoors or in the bathroom or held in the mother's lap. It could be laid flat or tilted to an angle of forty-five degrees. The child was supported on a broad surface and there was no danger of pressure. There was a minimum of restraint and the child could kick, wave his arms, and twist his body from side to side. If hot water bottles or blankets were needed they did not interfere with the apparatus. This particular frame would fit babies from seven to eighteen months of age.

Demonstration of Lesions of the Appendix Produced by Oxyuris Vermicularis.—Drs. R. L. CECIL and KENNETH BULKLEY gave this demonstration. They said that the importance of intestinal parasites as the exciting cause of appendicitis had been first emphasized by Metchnikoff in 1901, when he reported three cases, in all of which the feces were found to contain the ova ascaris and trichocephalus. In all three cases the administration of a vermifuge was followed by the passage of the ascarides and by the complete and permanent recovery of the patient without operation. From time to time various other writers had reported cases of appendicitis associated with ascarides. He had found reports of forty-seven cases where oxyuris was found in the appendix. The number of oxyurides present had varied from one to more than one hundred. Thirty per cent. of these cases were under fifteen years of age. Sixty-six per cent. of the cases were females. Erdman, Carson and others thought that oxyuris appendicitis presented a characteristic clinical picture Observers had disagreed concerning the actual rôle played by the oxyuris in the appendix. Oppe, Manasch and others thought that the movements of the worm could cause appendixicolic, but that they were incapable of causing definite inflammatory changes. Wagener, Metchnikoff, Higgins, Lewinson, and Winkler, who had investigated the pathological condition, claimed that these parasites might either predispose to bacterial infection of the organ by causing an erosion of the superficial mucosa, or they might burrow into the wall of the appendix and thus become themselves the exciting cause of the disease. The five cases of appendicitis associated with the oxyuris which they reported were from the surgical service of the Presbyterian Hospital. They all occurred in children under fifteen years of age. Four out of the five patients were females. The symptoms were about the same in every case, namely, acute onset with pain in the right lower quadrant, nausea, vomiting, and tenderness over McBurney's point. In two of the cases there was an absence of muscular rigidity. In three there had been previous attacks. All five showed a rise of one or two degrees in temperature and a moderate leucocytosis. The percentage

of eosinophiles was determined in only two cases. In one it was only 1 per cent. and in the other it was 44. The microscopic appearance of the appendix in all the cases was practically the same. The serosa was smooth but injected. On opening the appendix the lumen was found to contain bloody mucus in which were imbedded the oxyurides. The mucosa was swollen, reddened, and in two instances definitely ulcerated. Microscopical sections of the appendices showed an infiltration of leucocytes, chiefly eosinophiles and lymphoid cells. The veins were distended with blood and the leucocytes were loaded with blood pigment. The lumen of the appendix was filled with an exudate composed of blood, mucus and leucocytes. The inflammation was of the acute non-suppurative type The appendices showed a number of interesting lesions which had been produced by the oxyurides. They had been able to demonstrate these by cutting serial sections. An exhibition of these sections showed that oxyuris vermicularis might inhabit the appendix; that the male parasite was able to burrow into the mucosa and produce a focal necrosis, and definite inflammatory changes which consisted of hemorrhages into the tissue, infiltration of eosinophiles, and lymphoid cells and the usual phenomena of repair. There was some evidence that the oxyuris was a blood-sucking parasite. They hoped to make further researches on this point. It was their intention to study a large number of children's appendices with special reference to the oxyuris. The problems which they had set before themselves were: (1) The incidence of oxyuris in normal children's appendices. (2) The incidence of oxyuris in the appendicitis of children. (3) The determination of the percentage of the appendices containing oxyurides which showed lesions directly traceable to the parasite. They felt that the condition was one that was commoner than was supposed. The sections presented demonstrated that the thread worm could produce more than an attack of appendix colic; it was capable of boring into the wall of the appendix and of exciting there definite and characteristic lesions.

A Case of Diabetic Coma Treated with Maximum Doses of Bicarbonate of Sodium.—Dr. Francis P. Kinnicutt reported the case of a housemaid admitted to the Presbyterian Hospital on March 14 from whom it was impossible to obtain any satisfactory history previous to her present illness. For three weeks previous to her admission she had had extreme thirst, weakness, and loss of strength and weight. At the time of her admission she was stuporous, respirations were 24, full and deep, and suggested the respiration characteristic of a severe acidosis. The patient passed into a state of semicoma. The urine was examined and found to contain 3.50 per cent. of sugar, diacetic acid and acetone and also a trace of albumin and granular casts. At 7 a. m. alkaline treatment was begun, intravenously, by enteroclysis, and by mouth. During the first 24 hours 1,940 grains of sodium bicarbonate were administered and retained. In the next 24 hours 2,640 grains were successfully administered and in the following 24 hours 2,440 grains. From this time until her death at 5 o'clock the same day only small amounts could be administered. On account of a thrombosis of the veins used for intravenous injections they could not be used further. The coma gradually increased with the diminution of the quantity of sodium bicarbonate taken. The heart progressively failed until death occurred. During the period of the administration of the very large amounts of alkali the characteristic symptoms of a severe acidosis markedly improved and respirations assumed a more normal character, the patient was able to answer questions intelligently, and expressed herself as feeling better. A favorable outcome had been deemed possible, but with the inability to continue the administration of the alkali the deep coma developed. The total amount of bicarbonate of soda given and retained had rarely been exceeded in the treatment of diabetic coma. The laboratory studies of this case were of interest. The sugar content of the blood was estimated and amounted to 0.83 per cent. and 1.0 per cent. This was among the highest figures recorded. Any excess of 0.15 per cent. was regarded as hyperglycemia and among the highest figures recorded were those of Naunyn, 0.7 per cent. and Lepine 1.06 per cent. An analysis of the blood was also made to ascertain the fat content, .75 to .85 being normally present in the blood. Only in the severest cases of diabetes and when toxic symptoms were grave did lipemia appear. In such cases high values were exceptionally obtained, that was, from 4 to 5 per cent. Stadelmann once found 15 per cent. and Fischer 18.1 per cent. In the present instance the percentage of fat was below normal, .1092 per cent. In the great majority of cases of slight diabetes one found from one to one and a half grams of ammonia in 24 hours' urine; in severe cases 6 grams might be found. Ten grams were found exceptionally when coma was imminent. With the administration of a fixed alkali the amount of ammonia excreted might drop greatly. The ammonia in this case was found to be low in the 24-hour urine and similarly the total nitrogen, .845 gram and 4.25 grams respectively. The proportion of ammonia nitrogen to the total nitrogen excretion was 20.46 per cent., the normal being 2 to 5 per cent. In the absence of acidosis the relation between the total urinary nitrogen and the ammonia nitrogen was the same in diabetes as in health and was remarkably constant. With the development of acidosis the absolute and relative amount of ammonia nitrogen excreted was increased and might be regarded as an approximate measure of the acidosis. In the case under discussion, the examination of the urine at the time of admission showed 3.59 per cent. sugar and in subsequent examinations the percentage of sugar did not exceed 1.1 although the percentage found in the blood was 1 per cent. It seemed that there was an increased permeability of the kidneys to sugar as well as to nitrogen. The acetone bodies estimated by the citron test were 11.174 grams in the 24-hour urine. The pancreatic reaction (Cammidge's test) was positive.

A Contribution to the Study of the Metabolism in Arthritis Deformans.—Dr. David Bovaird said that one of the most interesting problems in general medicine was the study of the etiology of a group of cases characterized as chronic arthritis, not of infectious origin, not of gouty origin, but a term that was used for want of a better and more definite one. The prevalent theories regarding the origin of this condition were considered. Attempts had been made to obtain a specific organism as the causative factor, but none had been found. During the past two years a number of cases had been seen, so-called arthritis deformans, and an effort had been made to go into the metabolic changes of these cases. Nothing was noted concerning the phosphorus metabolism, but the metabolism of calcium was marked, there being found a retention of this element. A diet containing the least possible amount of calcium, one suggested by Dr. Wolf, was given these patients; the caloric value of the food and the calcium content were reduced to the least possible amount, and the patients were kept on this for months. The polyarthritis diminished to a certain extent; as a rule, none of the patients were injured by this treatment and all seemed to be somewhat benefited. The coagulation time of the blood in all of the cases reported was normal.

Dr. Francis P. Kinnicutt said that he had had *x*-ray pictures taken at intervals during the treatment of these patients and, so far as one could judge, the bone lesions were unaffected; this was perhaps what was to be expected.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held at Detroit, Mich., September 13, 14, and 15, 1910.

THE PRESIDENT, DR. FRANK P. NORBURY, HOSPITAL, ILLINOIS, IN THE CHAIR.

AFTER invocation by Rev. Edward H. Pence, and addresses of welcome by Hon. Philip Breitmeyer, Mayor of Detroit, by Dr. J. H. Carstens, President of the Michigan State Medical Society, and by Dr. A. D. Holmes, President of the Wayne County Medical Society, which were responded to on behalf of the association by Dr. Edwin Walker, Evansville, Ind., the Medical and Surgical Sections convened for the reading and discussion of papers.

Pain in Abdominal Diseases.—Dr. WILLIAM M. HARSHA of Chicago stated that in order to interpret pain properly, a careful history of the case was necessary, as pain must be considered in relation to other factors in a given case, and without these it lost its chief importance. The relation of pain to taking food was also of great value, particularly in duodenal or gastric ulcer or the various stenoses, benign or malignant. The direction and extent of painful radiation and the association with the hyperesthesia, local tenderness, and muscular rigidity were of the greatest importance both as indications of the site and gravity of the lesion. The arm pain in angina pectoris, the shoulder or upward radiation in gall-bladder disease, and downward, forward, and testicular pain in nephritic colic were well-known examples. The pain of abdominal disease might be either spontaneous or elicited by pressure, body movement, or position, and it might be influenced by psychical, thermic, mechanical, or chemical means, all of which might be utilized in cases to aid in exact diagnosis. Diseased viscera caused pain at or near their various sites, but there were many exceptions which lent importance to the reflex or referred pains. In most visceral lesions there was a disturbance manifested variously by pain, tenderness, hyperesthesia, or muscular rigidity on certain areas of the external or protective portions of the body. As moderate shock or fright would emphasize a vanishing or latent pain, he had tried the faradic current in suitable cases, and in two instances he had been able to locate more definitely the trouble. A great majority of abdominal diseases, especially of the more acute variety, were first heralded by pain rather than by change of size, position, or other physical conditions. The surgeon could often gauge the urgency in a given case by the character and severity of pain. Taking cognizance of the value of pain associated with local distensions and peristalsis, or the absence of peristalsis, they might locate a stenosis or other forms of obstruction, calling to their aid submerged palpation, or palpation in the bath, which would enable them to detect induration which was otherwise not palpable. By observing the time relation of pain to other symptoms, the effect of food, drugs, cathartics, cold, fatigue, movement, position, jarring, fist percussion, anesthetics, or electric stimulation, they should be able to increase the percentage of correct diagnoses. The safety of abdominal section might have caused them to relax their efforts at exact diagnosis. It had happened many times that laparotomy had been done for appendicitis when a movable kidney, pyelonephritis, ureteral stone, typhoid fever, diaphragmatic pleurisy, salpingitis, or other conditions were present. Age, sex, occupation, or previous history might give valuable aid. In childhood intestinal troubles prevailed, and they were likely to encounter appendicitis, intussusception, or tuberculosis, and in advanced age malignant disease. In women the pelvic organs were frequent sites of disease, while gallstones were more frequent. Lead colic might simulate organic disease. A history of indigestion, with vague epigastric pain, might aid in determining a perforation of the duodenum or stomach, and a record of previous inflammatory trouble in the abdomen might explain a sudden intestinal obstruction. Among the less frequent conditions might be mentioned the meteorism with abdominal pain, resulting from the embarrassed portal circulation in cardiac insufficiency. He had recently seen a case of this kind where the pain was so pronounced and distention so great that abdominal tumor was suspected by one physician. They should consider the possibility of disease of the central nervous system, such as tabes, herpes, or hysteria, disease of the spine, as caries, or spondylitis deformans. They should also consider the possibility of disease of the thorax, referring pain and rigidity to the abdomen, or of one kidney, referring the pain from stone to the opposite side. Excluding pain from the cord, spine, or reflex causes, they should remember that diseased viscera might be at the normal site, displaced especially by prolapse, or transposed. On the surgeon fell the burden of responsibility for exact diagnosis, as his operative experience should add to his knowledge.

Dr. WILLIAM FULLER of Chicago said the man who could best interpret the significance of pain was the one who had suffered some pain. While he did not think it was necessary to have all the acute abdominal diseases in which there was great pain to make a diagnosis, he thought a little knowledge gained in a practical way helped out very much. He stated that Dr. Harsha's paper contained two excellent points. First, was the emphasis that he laid upon the fact that abdominal pains might be severe even in trivial abdominal affections. Second, very serious abdominal affections might be unattended by pain.

Dr. CHANNING W. BARRETT of Chicago stated that when a patient complained of pain generally over the abdomen from appendicitis or gall-bladder trouble they found frequently that by putting the finger upon the point that was affected or supposed to be affected and making a little pressure it caused the surrounding pain to disappear. They could then go over the rest of the abdomen, and while the patient might complain of local pain, the rest of the pain was gone. Another point in regard to eliciting pain before the anesthetic was given. An anesthetic was of great value sometimes in pelvic conditions and abdominal conditions, but he thought they gained more knowledge of pelvic and abdominal conditions by examining the patient first without an anesthetic, finding out all they could, and they found then in giving an anesthetic some things that were apparent before the anesthetic had disappeared.

Dr. L. W. BREMERMAN of Chicago stated that in diseases of the kidney or the ureter, he had seen cases in which there was hematuria, with marked pain over the region of the kidney, the kidney being felt on palpation, with excessive tenderness over the kidney; a kidney lesion was diagnosed, and surgical intervention recommended. Upon cystoscopic examination of the individual, he discovered that the hematuria was developing from the supposedly healthy kidney, the urine from the supposedly diseased kidney being normal. Every method of examination should be resorted to before an absolute diagnosis was made.

Dr. HARSHA said the thing that most impressed him in studying this subject was the need of considering three or four different sources of abdominal pain. First, the central nervous system; second, the spine; third, the reflexes, and fourth, the visceral diseases themselves.

The Cause and Significance of Tubal Rupture in Extrauterine Pregnancy.—Dr. CHANNING W. BARRETT of Chicago read a paper on this subject in which he drew the following conclusions: 1. Pregnancy, which was considered to be always extrauterine in the beginning assumed pathological significance when it underwent ectopic attach-

ment. 2. The ovum attached in the tube had a parasitic action, having a malignant tendency in that it destroyed maternal tissues, embedded itself in the tube wall and tended toward death of the mother, but in "making its bed dug its own grave." 3. The growth of the ovum or enlargement of dead ovum mass together with the destruction and thinning of the tube wall led to almost certain rupture of the tube. 4. The primary rupture might be partial and even slight, or it might be complete and even fatal. 5. If complete, a subsequent rupture or subsequent ruptures were the rule. 6. With rupture free hemorrhage more or less severe occurred, which was never to be looked upon lightly and which might prove fatal. 7. The loss of blood might be through one rapid fatal hemorrhage or there might be a series of lesser hemorrhages. 8. If the patient did not succumb to loss of blood the presence of the blood and the ovum in the abdominal cavity acted as irritating foreign substances leading to loss of function and pathological changes in the viscera, and perhaps to local or general infection, thrombosis, embolism, etc. 9. The dead ovum was only slightly less harmful from the standpoint of infection. 10. A study of the pathology made all treatment looking toward killing the ovum appear irrational. 11. Patients in good condition with or without ruptures were almost certain to have future trouble and should have an operation as soon as was consistent with good work. 12. Patients in bad condition with concealed hemorrhage from the cause in question had collapse in proportion to the amount of blood lost, and rational treatment must look with certainty toward the stopping of further hemorrhage. 13. An opening of the abdomen with clamping or ligature of the vessels was the only reliable means of controlling internal hemorrhage, and if done rapidly and with care was little tax upon the patient. 14. The clinical experience of the world and a study of the pathology of this condition pointed to the danger of delay. 15. The more desperate the case while the patient yet lived, the greater the call for immediate action.

Dr. Edwin Walker of Evansville, Indiana, said he fully agreed with the essayist, and so far as his personal knowledge went, he knew of one death from repeated hemorrhages; but most of the deaths had been in delayed cases in which sepsis had occurred after operation. The teaching that they should wait in these cases was not sound. He felt that the position taken by Robb was untenable. Those patients that had been operated upon promptly in his experience had recovered.

Dr. Joseph Rilus Eastman of Indianapolis said this was 1910, and it was a pity that it was necessary for Dr. Barrett to present a paper like the one he had read. The teaching that it was wise to allow a woman to bleed into her own abdomen, or into her tube or uterus, while the surgeon stood by with his arms folded and fell back upon soft pillows or relied on Providence, was absolutely pernicious. If a vessel were bleeding upon the surface of her body, what man would be so negligent or so indolent as to stand by and allow her to bleed to death?

Dr. Charles Stoltz of South Bend, Indiana, stated he thought the more energy they expended in teaching that these conditions were to be met and not dallied with the better. The men who had received the proper teaching would recognize these conditions, and they would usually find some one who was competent to meet the conditions speedily, or they might be competent to operate themselves, because if there was any delay, or if the patient was carried from one place to another, she might just as surely die in one community as another. He did not know Robb, who said that shock meant nothing but hemorrhage, but if he made that statement he wanted to forget it, as he would rather act upon the theory that shock was hemorrhage, and hemorrhage was shock.

Special Points in Advanced Extrauterine Pregnancy.—Dr. Shelby C. Carson of Greensboro, Alabama, in this paper directed special attention to the control of hemorrhage during the operation. Although his experience was nil, he ventured the suggestion that the operation for advanced extrauterine pregnancy be done in two stages when necessary or advisable, at an interval of forty-eight to sixty hours, according to the judgment of the operator. In the first place, let the abdomen be opened, the child delivered, the iliac tightly compressed by metal bands, and further, to be doubly sure, the ovarian and uterine arteries clamped by rubber-covered forceps, if they could be approached. In the second stage, separate the sac, release the blood vessels after ligating the anomalous ones, and closing the abdomen. Sometimes hysterectomy was imperative. This differed from and apparently was superior to the old method of uniting the sac to the incision and waiting weeks for its separation, since by this method the danger from sepsis was eliminated.

Dr. J. H. Carstens of Detroit stated he had one woman that went to term, a general practitioner having made the diagnosis. He operated on her in two stages. The placenta seemed to be attached to the intestines and the rectum, and he did not have the courage to remove it. He thought the best thing would be to leave the placenta alone, and so he removed the fetus, separated the peritoneum with the sac, and drained. The woman was septic at the time of operation, and finally died from sepsis. The placenta did not separate. Little shreds came away through the abdominal incision.

Dr. William M. Harsha of Chicago said he had never heard satisfactorily explained the cause of the intense pain that came on in cases of tubal rupture. The extent of pain and the broad radiations of it were great in comparison to the very small area apparently involved. A woman with tubal rupture suffered pain from her chest to her thighs—sometimes, at least. The broad radiations, with the intense character of the pain, made it almost impossible to get from these patients a rational explanation or history. These were the cases in which he believed a good dose of morphine was indicated. It would first abolish the cardinal or reflex pains to a certain degree and help to localize the trouble. Second, it would limit the hemorrhage, but before administering morphine one should observe carefully the character of the pain, the extent of the radiations, the time, and the urgency of the condition. After recognizing these, morphine would answer two indications, namely, to relieve the shock and put the patient in a better condition for operation, and to some degree arrest the hemorrhage.

Dr. Channing W. Barrett of Chicago said in regard to dealing with extrauterine pregnancy that was advanced, they found that in the early months the ovum was not considered. The probabilities were that so far as the ovum was concerned it would die, and the chances were that it would kill the woman sooner or later. A few years ago they would have said that at any time during the extrauterine pregnancy, early or late, the ovum should be removed at the earliest possible moment. The teaching had been that if the ovum had passed the fifth month, or along about there, they should wait for viability. He would be inclined yet, even in spite of that teaching, to remove the ovum when found, if it had reached a viable period, looking to the interest of the child and mother.

Requirements and Limitations of Nitrous Oxide and Oxygen Anesthesia.—Dr. Charles K. Teter of Cleveland, Ohio, said the greatest advancement in general anesthetics made in recent years had been the development and use of nitrous oxide and oxygen in major surgery, and in general surgery he had seen within the past few years nitrous oxide and oxygen come from a very limited use to one of almost unlimited application. He had been

one of the foremost in advocating the superiority of nitrous oxide and oxygen as an anesthetic. He had been compelled to do so because of the almost phenomenal success he had had with it. He had administered nitrous oxide and oxygen over sixteen thousand times in all conditions and for almost every conceivable operation, and having had this practical experience, which alone was essential to appreciate the excellency of this agent, he wished to give the profession the benefit of it. It was freer from post-anesthetic complications than any other general anesthetic known. It was by far the most difficult general anesthetic to administer because of the following reasons: 1. The physical properties of nitrous oxide were such that this gas must be given from 80 to 90 per cent. pure, in order that a sufficient saturation of the gas in the blood might be had to produce that change in the nerve cell which brought about the anesthetic state. 2. The anesthetic properties of nitrous oxide and oxygen were extremely evanescent. The patient could pass from complete surgical anesthesia to a conscious state within sixty seconds. The extreme rapidity of induction and elimination made the administration of this anesthetic difficult. 3. Muscular tone was maintained to a much greater extent than it was under ether or chloroform, due probably to an increased percentage of carbon dioxide in the blood. The requirements for the proper administration of nitrous oxide and oxygen were: 1. A thorough understanding of the technique of administration and action of nitrous oxide and oxygen. 2. The apparatus must be accurate, have attachments for the administration of other general anesthetic agents, and be easily sterilized.

Dr. L. W. Bremerman of Chicago said that in his special work, which dealt entirely with the bladder, the ureters, and kidney, or conditions involving the genitourinary tract, he had employed as a general anesthetic a combination of nitrous oxide gas and oxygen exclusively during the last two or three years. As it became necessary to perform major surgical operations upon the aged, particularly for the removal of the prostate, he could not recommend more highly any other anesthetic than the use of nitrous oxide gas and oxygen. It produced none of the untoward after effects, such as nausea and vomiting. The patient was usually awake before he left the operating room. It had a great tendency to reduce the shock of the operation by shortening the length of the anesthetic, and in his hands it had given perfect satisfaction.

Dr. Fenton B. Turck of Chicago said that some years ago he conducted a series of experiments on animals with chloroform and ether with a view of determining the changes that occurred in the blood. It was found by these experiments that there was a loss in the antibodies and ferments in the blood, and that there was diminished resistance to bacteria, as was shown by the agglutinins, precipitins, and other substances which were found in the antibodies in the blood. It was found that these animals went into shock very easily in which there was a lowered condition of the blood. These experiments showed the effects of ether and chloroform on the serum itself, and two conclusions were arrived at, one being that there was an actual direct chemical effect on the serum, and the other was that biological changes took place and acted on the cells as toxins.

Further Observations on Acetabular Fracture with Intrapelvic or Central Dislocation of the Femoral Head.—Dr. William Fuller of Chicago detailed two cases of this class of fracture and presented for consideration a few points in a general way pertaining to this important but, as yet, imperfectly understood subject. So close was the relation between fractures and the changes that took place in the bone, whatever they might be, that all such injuries resulting from trivial or slight degrees of violence should be regarded as possibly belonging to this class. Efforts had been made by several observers to put the etiology of fractures on a physical basis by studying the mechanical capabilities of bone. The great strength of the pelvic bones, their peculiar and powerful articulations and liberal muscular supply, were factors which singly and combined contributed much to the neutralization of all forms of direct violence exerted on this portion of the body. While Katz's theory of the mechanism of certain acetabular fractures would probably hold good, it was also worthy of mention that the experiments of Kusmin demonstrated that this fracture could or would not occur unless the force be applied with the femur in abduction. When the legs were kept parallel the acetabulum remained unfractured. From impacted fractures of the femoral neck central dislocation of the femoral head might be differentiated by the age of the patient and the comparatively high degree of injury in the latter instance. The remarkably sunken appearance of the greater trochanter and its slightly altered relation to Nelaton's line were points which distinguished the dislocation. The certainty with which the femoral head might be palpated in either of the anterior dislocations of the femur and its increase in length in the thyroid dislocation would serve to differentiate any one of these dislocations from a central one. In the dorsal dislocation, especially to one above the obturator internus tendon, the trochanter was far above Nelaton's line, the thigh was adducted, flexed, and the axis of the dislocated femur crossed the lower end of the opposite one. Moreover, in the simple dislocation all movements would be less free than when the head and neck occupied a central position. It was not intended that the symptoms of acetabular fracture as here given were in the least to minimize the importance of the radiograph, but that each and every manifestation of all hip injuries, of whatever nature, should be carefully and cautiously considered. In no instance should the clinical findings settle the diagnosis, as they were frequently misleading, and the conclusions based thereon should invariably be corroborated by the roentgenologist. In case of failure to replace the head of the femur within the acetabulum, operative interference might offer the only hope of satisfactorily dealing with such a condition; but the particular type of operation and the advantages to be gained by it would depend much upon factors opposing the reduction.

The Rôle of the Bacillus Coli Communis in Acute and Chronic Dilatation of the Stomach.—Dr. Fenton B. Turck of Chicago presented some facts with reference to the rôle of the *Bacillus coli* in the gastrointestinal tract in producing lesions in the liver, kidney, stomach, and other organs. Experiments were begun with intravenous and intraperitoneal injections into dogs, rabbits, guinea-pigs, and rats. The results obtained were variable and inconstant. On feeding animals with bouillon cultures of the *Bacillus coli* daily over a period ranging from three to fourteen months lesions were found in the stomach, duodenum, liver, kidney, brain, and spinal cord varying according to the methods, quantity, and character of culture. It was found that animals fed with cultures of *Bacillus coli* would acquire acute or chronic dilatation of the stomach by overworking or overloading that organ. Examination of the blood showed that it remained sterile during the experiments, and the heart's blood at death was also sterile. In feeding cultures of the *Colon bacillus* pronounced changes were revealed in the blood and tissues. Agglutination of *Bacillus coli* by the dog's serum was noted, hemolysis of the blood was evident; cytolysis and autocytolysis of the cells of the mucous membrane of the stomach, kidney, liver, and other organs were marked on microscopical examination. The picture was not one of reaction to an infection, but rather a systemic condition of induced cellular change. To obtain spontaneous, acute, or chronic dilatation of the stomach in

animals it is necessary to first feed the animals with cultures of *Bacillus coli* over a long period of time, followed by over-use of the stomach, especially increasing the intragastric pressure. Acute and chronic dilatation of the stomach was due to the fatigue of the gastric muscles. The author pointed out the indications for treatment in acute dilatation of the stomach. The usual methods of treatment were gastric lavage; diet, frequent but light meals; drugs, such as tonics, laxatives, alkalies, or acid, as indicated; electricity and exercise; hydrotherapy, balneology, rest, anr recreation. In case of failure of the above methods surgical operation was indicated. For the last seventeen years he had followed these indications and methods: (1) Reduce the fatigue of the gastric muscle by rest, followed by appropriate exercise of the gastric muscle, inducing normal peristalsis. (2) Sterilization, as far as possible, of the gastrointestinal tract. (3) Restore the integrity of the splanchnic circulation.

Gastrostomy as a Curative Measure per se in Non-malignant Strictures of the Esophagus.—Dr. JOSEPH RILUS EASTMAN of Indianapolis said the directly beneficial effects of gastrostomy in cases of so-called benign strictures of the esophagus were not generally appreciated. They had been too slow to break away from old notions, which were developed in the preaseptic era, when the performance of gastrostomy was attended with considerable danger. Ewald, in discussing a report of successful dilatation of a diphtheritic stricture of Rosenheim referred to a peculiar observation which he had made in dealing with such benign stenoses, namely, the remarkable circumstance that cicatricial strictures for which gastrostomy had been made nearly always improved steadily after the stomach fistula had been provided and food had been introduced through the fistula instead of through the gullet, that is, the stricture gradually developed a larger caliber without any other treatment whatsoever. Ewald explained these phenomena in the following manner: After the gastrostomy was made it became possible to fill the stomach with food. The pull of the full stomach downward gradually stretched to some degree the elastic esophagus. When the stomach became empty the downward pull ceased, then the pressure of the food mass above the stricture had its effect upon the stretched and more yielding strictured segment. More compact masses of food might then squeeze through. The explanation of the phenomena given by Ewald could hardly be applied to all cases. After the swallowing of a hot or caustic fluid the mucosa of the gullet might become deformed in many ways. Among many interesting deforming processes are, for example, the complete tube cast-like separation of the mucous membrane described by Strauss, the esophagitis desiccans superficialis of Rosenberg, and esophagitis exfoliativa. In these conditions, after the mucosa had become loosened from the underlying tissues and thrown into folds or ridges, or pockets it was easy to understand that the passage of food or of a bougie must be attended with great mechanical difficulty. It also seemed fair to believe that the downward traction due to the filled stomach must have the effect in some instances of smoothing the valve-like folds and irregularities of the loosened membrane, thus permitting the passage of food through a previously impassable esophageal lumen. The gastrostomy was curative *per se* for another and more important reason. The rest afforded the esophagus was of the greatest value in allaying the inflammation which preceded or attended practically all benign strictures. If ulceration was present the passage of food, or, what was worse, the arrest of food, with consequent fermentation, must maintain or increase the activity.

Fracture-Dislocation of the Atlas and Axis.—Dr. CARL E. BLACK of Jacksonville, Ill., reported a case in which operative reduction was adopted. He called attention to the essential diagnostic points and gave some reasons why operative interference had not been adopted more frequently. He summarized the treatment of such injuries as follows: (1) Immediate reduction under an anesthetic. Walton had his patient sit in a chair while he turned the head still farther from the dislocated side. The head was then tilted to the sound side and extended while the column was rotated back into place. Hueter's method by rotation might be used. When the atlas was dislocated, before any method of reduction was undertaken, they should be sure that the odontoid process was not fractured. If the odontoid process was fractured they were advised by some to follow the second indication and place the patient in a plaster cast, which would immobilize the seat of injury until healing could take place, and then reduce the deformity. The objections to this plan are that it failed to give the patient any opportunity of relief before degeneration of the cord could take place, and subjected him to further pressure from callus, and finally it would usually be found impossible to effect reduction after so long a time. The third plan was operative interference. While considerations of the cord were all important in such injuries they should not be deterred from making every reasonable effort to restore the dislocated or fractured spinal vertebræ, because many questions regarding the degeneration and regeneration of the cord were in the stage of controversy and remained unsettled. It would seem to be their plain duty to effect a restoration of the bony column as far as it could be done without further endangering the cord, except in those cases where the cord was hopelessly crushed beyond the possibility of the recovery of lost functions. The mechanical difficulties were great and often insurmountable, but perseverance, with reasonable efforts to overcome them, would certainly tell in time. It was a reasonable proposition that an injured cord had a better chance in a spinal canal with sufficient room than it had when held under even mild compression. For this reason the second indication should usually be omitted and the injured parts exposed thoroughly. If the case was one of dislocation efforts at reduction could be repeated under the direction of the eye and finger, and failing in this a laminectomy could be made. This mistake of the treatment of the case reported was a failure to appreciate the compression produced by the posterior arch of the atlas.

Preparation Required for the Practice of General Surgery.—Dr. G. W. GREEN of Chicago said the public had a right to demand of the surgeon: (1) A good foundation in the shape of a diploma from a good school. (2) Considerable time spent with a master of surgery, so that he had the following knowledge: (*a*) sufficient experience to make a correct diagnosis; (*b*) sufficient experience to know what it was best to do when a diagnosis was made; (*c*) that he should know just how to do the work and have enough practice to have a definite surgical technique of his own, so that he was capable of performing the operation he essayed or any complication which might arise from that operation in an average length of time; (*d*) that his mortality should be as low, and his postoperative results as good, as those of the average surgeon. In return the surgeon had a right to expect a fair remuneration and respect from the public, but no more than any other member with equal qualifications specializing in any other branch of this, one of the noblest professions on the face of the earth.

Tuberculosis of Bones and Joints.—Dr. EDWARD M. BROWN of Chicago read an exhaustive paper on this subject. Among other things, he said: The treatment of tubercular joint disease was (1) general or constitutional; (2) specific or serum treatment; (3) local. For practical purposes the local treatment might be divided into injection treatment, mechanical, and operative. The advantages

of operative treatment were: (1) The disease could at once be thoroughly eradicated, or so nearly so that the patient easily overcame the disease. (2) Dissemination of the disease was prevented. (3) The treatment was shortened. (4) The general condition of the patient rapidly improved. (5) The length of the limb and function of the joint were preserved to the best possible degree.

The Responsibility of Physicians in the Traumatic Neuroses.—Dr. H. H. Drysdale of Cleveland, Ohio, in this paper discussed the history and manifestations of the traumatic neuroses in detail. In studying these conditions etiologically he had arrived at the conclusion that the true genesis, in a large majority of cases, was psychic, and that it was fright, fear of death, anticipated pain, and anguish received unexpectedly by a totally unprepared sensorium which was the chief element to be considered. Psychologically fright was a fundamental emotion. Violent in action, it would under certain conditions of mind pervert the sense faculty, disturb the kinesthetic equipoise, and deform the physical and psychical personality. He considered the manifestations of these conditions to be the involuntary expression of a break in the bodily feeling. These by degrees tended to organize and combined to form a morbid mental state, a delusive conception, as it were, toward which every though converged. A faulty environment frequently did more harm than the actual injury, as it tended to make the individual introspective and depressed, and as a consequence he threw aside the normal weapons of defence and surrendered himself to the misfortune which had assailed him. From an experience of 108 cases investigated from the standpoint of the corporation as well as that of the patient, and which included in many instances the prelitigation, also the postlitigation period, he had made several observations which he believed, if put into practice, would place the responsibility of adjusting these trying conditions on a scientific basis, and thus obliterate much of the confusion and disquietude which surrounded the traumatic functional disorders of the nervous system.

Hygroma of the Testicle.—Dr. Charles M. Harpster of Toledo, Ohio, in his paper stated a hygroma was essentially a serous cyst. The bacillus of tuberculosis was often found, and the hygroma, if a true one, always contained hard caseous masses and rice bodies. A true hygroma of the testicle and cord was rare. The case he related was a man, forty-five years of age, who for a number of years suffered from a hydrocele, and this was frequently tapped by his family physician. Some months ago it was tapped and considerable blood and some pus were withdrawn. This alarmed the patient, and in consultation with the attending physician he found the testicle considerably enlarged and very painful, with some slight general disturbance. The cord and testicle were removed. Tubercle bacilli were found in the rice bodies and tissue of the sac. Syphilis undoubtedly had been contracted, but denied by the patient.

Dr. Richard Dewey of Wauwatosa, Wis., reported a case of manic-depressive insanity, with satyriasis, which was complicated by an abscess of the appendix. The starvation treatment was resorted to, followed by evacuation of the abscess and recovery.

Dr. Frank Smithies of Ann Arbor, Mich., discussed some of the newer methods for the detection of tubercle bacilli, with particular reference to the so-called antiformin method.

The Tubercle Bacillus Cultivated from Cases of Primary Tuberculous Cervical Adenitis.—Dr. William Litterer of Nashville, Tenn., in his paper stated nine consecutive cases of primary tuberculous cervical adenitis were examined, which resulted in the isolation of five cultures of *Bacillus tuberculosis* of the typus humanus and the four cultures of the typus bovinus. The classification of the types being made on the same basis of four tests, to wit, first, the morphological characters of the bacilli; second, the dysgenetic or eugenetic character of the cultures; third, the relative virulence toward rabbits, and fourth, the reaction curve in 5 per cent. glycerin bouillon. This latter test served admirably to distinguish between the two types, provided there were repeated application and careful control over a period, in some instances, of eighteen months. He had found that the differences in the growth of the two types, dysgenetic and eugenetic, on Dorcet's egg medium to be very valuable in differentiating the bovine from the human type of bacillus. Rabbit virulence had probably been more uniformly satisfactory than any of the tests in determining the differences between the two types of bacilli.

The Teaching of Clinical Psychiatry; a Medical Educational Problem.—The President, Dr. Frank P. Norbury of Hospital, Ill., said the subject of the address was chosen as a text in order to present certain imperative demands of medical education of to-day. What was sought was to utilize the opportunities at hand, develop new ones, create higher ideals, readjusting ethical educational standards. The fundamental fact of the present controversy regarding medical education was that it was a part of the educational propaganda of the century—a world movement. In this country this progress was based first on the integration of the educational system; second, the standardizing of undergraduate work; third, the standardizing of professional courses in medicine. Modern medical education was in the transitory stage in teaching clinical medicine. Clinical medicine to-day included the interpreters as well as the research workers. Medical sociology was the enlarged appreciation of the value of clinical medicine extended to the problems of etiology, preventive medicine, occupational diseases, and general and special civic problems. The scope and value of such work were unappreciated by the unthinking masses of the profession. Clinical psychiatry was prominent in this field of newer clinical activity. It was in contact with more points in life, its realities, its ignorance, its prejudices, its ethical discordance, and falsifications, than any other department of medicine. A real need existed to-day for the teaching of these master problems of the age. The teacher must be a biologist in its widest clinical interpretation, a sociologist, that he might grasp all etiological factors, and an internist, that he might be in touch with all of the physical factors entering into the problem. Modern medical teaching must give to the student the opportunity to see the whole at near range. The teaching of psychiatry was a state need, just as much as any other problem of preventive medicine.

Diagnosis of Surgical Lesions of the Kidney with Especial Reference to the Value of the X-Ray and the Cystoscope.—Dr. Louis Frank of Louisville, Ky., delivered the Address in Surgery. He said: Although the diagnosis of the character of new growths in the kidney might be impossible before operation the recognition of a surgical lesion and of the surgical indications were not, as a rule, attended with great difficulty, provided a thorough, painstaking, and complete examination of the individual was made. In renal calculus they had at hand means for physical examination which in the presence of even very obscure symptoms would render the diagnosis in most all cases practically certain. These were the cystoscope and the radiograph. The cystoscopic examination frequently showed a swollen ureteral orifice. The passage of the ureteral catheter would at once reveal from which kidney the blood or pus in the urine was coming. The cystoscope was not nearly so valuable an aid as the röntgen ray. It did reveal whether or not one kidney alone was involved, or whether or not a kidney had ceased to functionate. Although secondary in value in the diagnosis of renal calculus to the *x*-ray and to the clinical history,

the cystoscope should always be employed previous to operation as an aid in ascertaining which was the diseased kidney and the condition of the other kidney in regard to the character and condition of its excretions. As a confirmatory diagnostic means the greatest value of the radiograph was in connection with renal calculi. The predominant signs of most renal affections of a surgical character were pain, hemorrhage, urinary disturbance, and tumor. One or more might be absent or they might all be present in any given case.

The Modern Doctor, His Successes, His Failures, His Future.—Dr. JOHN K. MITCHELL of Philadelphia delivered the Address in Medicine, and among other things said: A time would come, since the disappearance of all disease was unlikely, when governments would make a more organized contest against it, would teach and enlist all physicians in a common army as they now educated and paid the soldier. This must come, because with improved sanitation and the constant advance of preventive means illness would grow infrequent, so that unless he was a paid servant of the state the physician would not be able to exist. When that army was enlisted the occurrence of preventable diseases would be as much a matter for court martial and the punishment of the person who allowed it to pass him as the failure in duty of a soldier asleep at his post. In that golden future in which sickness would be as rare as war was now instead of being a single-handed fighter the doctor would serve as an enlisted man in the great battle for life and strength against illness and pain; he would have no new duties, perhaps, but new powers, ability to enforce obedience to laws of health, until, under wiser ways of life, death, the one unmedicinable disease, came only to the aged, approaching without notice, to be met without fear, bringing an ending peaceful and calm after an active life and a quiet old age.

Myositis Ossificans Progressiva.—Dr. ARTHUR R. ELLIOTT of Chicago presented the clinical history of a case of this disease, showing *x*-ray pictures which clearly demonstrated the bony deposits in various muscular areas. The patient, a girl of seventeen, first displayed symptoms of the disease at the age of two. The involvement of the muscular system was widespread, resulting in many deformities, and much restriction of movement. The general health had not as yet been greatly affected. Congenital malformations of the hands and feet existed, such as were observed in about 75 per cent. of recorded cases. This clinical record was the one hundred and second in the history of the disease since the first case was discovered by Fuke in the "Philosophical Transactions" in 1740. The etiology and pathology of the disease were briefly discussed.

Neurological and Psychiatric Aspect of Tuberculosis.—Dr. CHARLES H. HUGHES of St. Louis stated too much attention had been devoted to the classical form of lesion of pulmonary tuberculosis and too little to the other conditions of the organism, especially to the state of the nervous system and what impression was made upon the patient's mind. He was dealing somewhat with the detrimental effect of adverse psychical suggestion, and he wished to enter a protest and be as emphatic as he could against the pronouncement positively, where it could be avoided, of a diagnosis of tuberculosis to the patient in its earlier stages, and the putting of the patient upon the outdoor treatment alone of tuberculosis. He entered his protest against ignoring the detrimental effects of psychical suggestion and would speak of the beneficial effects of it in the treatment of pulmonary and other forms of tuberculosis. To tell a patient, when he had his first hemorrhage and the microscope revealed occasional tubercle bacilli, that he had tuberculosis and must sleep out of doors, or in a cold room, with his body well wrapped, or sleep with his face out of a window in all kinds of weather for the purpose of giving him fresh air, a thing to which he had never been accustomed, exerted a detrimental influence, an adverse psychical suggestion, and was a most potent influence in determining the fate of that individual. He had in mind a case that came under his observation. A friend of his was sent to Colorado at the time of his first hemorrhage. He was a vigorous man, but led a sedentary life. He neglected those physical influences that were necessary to rejuvenate the blood and increase its vital resistance, to build up the metabolism, and improve the cytological processes. He went to Colorado under the psychic impression that he was affected with pulmonary tuberculosis, a sort of suggestion which sealed the fate of more patients than those who suffered from tuberculosis. He went there, occupied a cold room, and slept with his head out of a window, with a cage arrangement so as to screen himself against mosquitos. He declined steadily. He was dead now, although he went there as a strong man physically. The adverse influence on that individual of psychical suggestion sealed his fate—at least, prematurely. If the diagnosis and possible prognosis had been withheld in that case in his opinion, from what he knew now, the man might have been living to-day. The man who hastened to give a localized and fatal prognosis in a case did not thoroughly comprehend the influence of mind over organisms. He did not fully comprehend the influence of the higher psychic centers over the lower centers of metabolism, upward or downward. True therapeutics depended upon exalting the metabolisms of the organism and not in depressing them. Not enough attention was given, from a psychotherapeutic standpoint and from a neurotherapeutic point of view, to take care of the isolated nerve centers of the tuberculous patient, and in order to accomplish that his digestion must be aided by continuous and unremitting hyperdigestion, artificially enforced, and an amount of sleep adequately secured.

Pulmonary Tuberculosis and Syphilis with Brief Reports of Three Cases.—Dr. ROBERT H. BABCOCK of Chicago cited the views of different writers as to the mutual influence on each other of the association of these two infections and showed that the effect of the second infection depended largely on the stage of the primary disease. He then narrated the salient points in three instances coming under his observation in the past year in all of which pulmonary tuberculosis was developed in the late stage of syphilis with apparently a retarding effect on the tuberculosis. His conclusions were as follows: 1. The effect of the association of pulmonary tuberculosis and syphilis seemed to depend largely upon the stage of the primary disease during which the second infection was acquired. 2. The acquisition of syphilis during the incipient or early period of tuberculosis appeared to be of a negative influence or even in some instances to exert a retarding or curative effect on the tuberculosis. 3. Syphilis acquired by a consumptive in an advanced stage was likely to aid the downward progress of the tuberculosis. 4. Tuberculosis when developed during the primary or secondary stage of syphilis offered a bad prognosis and was apt to run a rapid course. 5. When pulmonary tuberculosis developed during the third or late stage of syphilis, it was apt to pursue a slow course, probably because of the tendency of the lues to sclerosis during this stage. 6. The association of these two diseases did not preclude the mercurial treatment of the syphilis by intramuscular injections and inunctions, but iodine if administered at all must be used cautiously because of its tendency to hasten softening of the tuberculous foci. 7. During the antisyphilitic medication there should be no relaxation in the hygienic measures recognized as necessary in the management of the tuberculosis.

Preliminary Report of Cases Treated by Dr. Carl Spengler's Tuberculosis Immune Blood.—Dr. W. F. WOOLSTON of Chicago said Spengler had pointed out that

in previously immunized patients, after an injection of an antigen, the following relative change in position of the stored up immune substances took place: In about half an hour the quantity of serum immune substances increased, with a decrease in the immune substances of the red blood cells; and in a few days the deficiency in red blood cells had again been balanced or overbalanced and the serum left deficient of these bodies. Dr. Spengler was of the opinion that the leucocytes played a part in the absorption of these bodies. It would be seen that he regarded the erythrocytes as the main source of the production of immune bodies. In healthy animals after tuberculous poison had been injected the immune bodies were demonstrable in the red blood cells. They appeared to be adherent to the hemoglobin and could be separated chemically or mechanically. He had not as yet, with the limited time and number of patients, been able always to say beforehand just which cases would improve. However, the acute miliary had shown the most striking results, as health had been regained in a comparatively short time. Some of the chronic cases had shown no improvement and two of them seemed to have old lesions stimulated to activity. Some of the untoward effects had been a diarrhea which had been easily controlled by some mild intestinal antiseptic. In a case of one nine-year old patient a rash occurred after the first injection which disappeared in twenty-four to thirty-six hours. Among the earliest signs of improvement were the disappearance of lassitude, an improvement in the appetite, a decrease in the amount of sputum and number of bacilli, a gain in weight, an improvement in sleep, and a lowering of temperature and pulse. The toxic pulse, however, took more time to reduce, and sometimes heart stimulants were indicated to aid in the myocardial power. The conclusions of writers who had used this tuberculosis immune blood serum were favorable as to its efficiency.

Prostatic Hypertrophy.—Dr. JOHN E. CANNADY of Charleston, W. Va., in his paper stated prostatic hypertrophy was the greatest curse of age in man. The chief indications for operative relief of obstruction were difficulty in urination and residual urine. He spoke of the value of bladder irrigation and the administration of urotropin and sodium benzoate. This combination was well borne by the stomach. Matters of diet and water drinking were of paramount importance. The choice of operation, whether suprapubic or perineal, depended largely on the individuality of the operator. The value of suprapubic cystotomy was pointed out. He spoke of Hunter McQuire's method and emphasized the necessity for rapid work. The popularity of the different methods was largely a matter of geography, like chloroform and ether. He spoke of the results of Freyer and Young, and pointed out the advantages of a non-toxic local anesthetic, such as novocain in doing a cystotomy. Only a brief general anesthesia was necessary for the completion of the two-stage operation. He spoke of the management of the patient before, between, and after the various steps of the operation. They should always bear in mind the conservation of the patient's strength. The two-stage operation cut the danger in half. Normal saline irrigation was of great value. The end results were almost ideal in the average case, there being both anatomical and physiological restoration of urethra and bladder. He reported illustrative cases showing the management of the normal case.

The Interpretation of Jaundice.—Dr. CHARLES N. SMITH of Toledo, Ohio, gave an interpretation of jaundice as observed in gallstone disease and its associated conditions—the interpretation of a symptom which was both infrequent and inconstant, and, at best, indicative only of complications, or terminal events.

Dr. J. H. CARSTENS of Detroit said the common everyday catarrhal jaundice was of great importance. It was caused by gastroduodenal catarrh so-called. A patient would have jaundice and in the course of five or six weeks it would disappear, and whether treatment had any effect or not he had grave doubts. He had had this form of jaundice himself. He took everything his physicians told him to take—sweet oil, calomel, and many other things, but the jaundice continued. He then restricted his diet to nitrogenous food, and did not take any kind of carbohydrates, oils, fats, etc., but some good lean beef, some eggs and water, and in a short time the jaundice disappeared.

Dr. R. N. MURRAY of Flint, Michigan, stated after suffering from jaundice for a considerable period of time and having tried various remedies, at the request of some Flint physician, he took ammonium chloride in ten to fifteen grains every two hours, and in four days the jaundice cleared up.

A New Principle in the Treatment of Graves' Disease.—Dr. GEORGE W. CRILE of Cleveland said the benefits which followed the ligation of the superior thyroid artery were due, for the most part, to the break of the nerve supply which was inevitable in the course of the ligation. In Graves' disease the thyroid showed a work hyperplasia, and the brain cells showed a work exhaustion. In Graves' disease the brain sent a more or less constant flow of stimuli into the thyroid gland. The thyroid responded by an increase of its secretion. This increased secretion of the thyroid caused an increased activity of the brain cells. In this manner the brain and the thyroid reciprocally goaded each other, and this deadlock, if not broken, continued until one or the other was worn out. This, he believed, was the explanation of the curious ending one occasionally observed, namely, the sequence of myxedema and Graves'. Breaking of the nerve connection between the brain and the thyroid gland rendered Graves' disease curable. No case of Graves' disease was cured by operation alone, and no case was cured until the thyroid gland and the brain were both restored to the normal. This was best secured by operating in such a manner that there was no excitation of the nervous system, nor of the thyroid glands; hence no volatile outburst during or after the operation, and no operative danger; then placing the patient in a rest cure for a month or more, depending upon the severity of the disease. If, on the other hand, the patient after the operation was at once immersed in the environment in which the disease originated, there would be many disappointments. The plan of treatment by a combination of a benign operation, followed by a prolonged rest cure, would restore the patient in so far as tissues were not already irreparably destroyed to the bloom of health.

Cleft Palate.—Dr. G. V. I. BROWN of Milwaukee read a paper in which he described the surgical operative steps in closure of cleft palate.

Surgery of the Great Sciatic Nerve.—Dr. B. M. RICKETTS of Cincinnati read a paper on this subject in which he reported two cases of complete severance with subsequent anastomosis. He drew the following conclusions: 1. Compression for sciatic neuralgia hardly justified the effort. 2. Acupuncture with the injection of electricity or medicaments through an open incision was to be recommended. 3. Acupuncture without open incision was most difficult and uncertain to accomplish. 4. The use of a metal wire and tube for direct multiple injections should be encouraged. 5. Stretching the nerve for neuralgia had been more or less beneficial, and second in choice before more radical measures were employed. 6. Neurotomy without suture was to be condemned, but it should be employed before sacrificing any of the nerve tissue. 7. Neurectomy was the last of surgical measures to be

employed for neuralgia. 8. Neurorrhaphy (primary or secondary) should be done in cases where the nerve had been partially or completely severed by any cause. 9. The great sciatic nerve might be completely divided and remain so indefinitely without great loss of sensation. 10. Both sensation and motion might be improved or completely restored by coapting the severed ends with sutures. 11. Small needle and silk were attended with less trauma than those of larger size. 12. Anesthesia might be local or general.

Office Treatment of Antral Disease.—Dr. WILLIAM W. PENNELL of Mt. Vernon, Ohio, said many simple forms of empyema were amenable to office treatment. The requisite amount of drainage could be made under cocaine anesthesia. There were cases where tooth extraction and curettement and closure of the alveolar fistula had to be practised, but these were made simpler by efficient drainage, astringent washes and cleanliness. Even the graver forms were made more amenable to radical operation where drainage and washings had been practised as preparatory treatment. After drainage had been established, washes of sterile normal salt solution were the only medicaments used in simple empyema; while in those having dental complications, extraction of teeth, and those having thickened antral membrane from prolonged inflammation, curettement, and the use of astringents, were added to the simple washes.

Surgery of Musculospiral Paralysis.—Dr. A. H. BARKLEY of Lexington, Ky., read a paper on this subject in which he drew the following conclusions: 1. Many cases had been operated on but comparatively few reported. 2. In cases of trauma associated injury of the musculospiral nerve might be and frequently was overlooked. 3. The anatomical position of this nerve rendered it peculiarly liable to trauma. 4. Injuries, such as fractures, falls, and blows, were the most frequent cause in the order named. 5. It occurred with equal frequency in both arms, the middle and lower third being the most often affected. 6. The musculospiral was injured more often than any other nerve and not infrequently served as ground for legal action. 7. More frequent in males and might occur at any age, more especially between ten and thirty years. 8. In cases where complete loss of sensation and motor function followed severe injury, the probabilities were that the nerve had been injured and operative interference was indicated. Cases following slight trauma often recovered without operation; however, if no improvement was noticed after two or three months, operation was justified. 9. Secondary cases sometimes presented technical difficulties not present in primary cases. 10. No one symptom was pathognomonic and the pathological condition varied so widely that it was impossible to state before operation with much certainty the exact condition present in a given case. 11. Prognosis was good in clean cases. Especially was this true where operation had been resorted to early. One of the most important determining factors was the length of time the injury to the nerve had existed. 12. Operative treatment depended on the individual case: the earlier the operation the better the result. Small round needles and fine silk had given best results in the hands of the writer. 13. All patients with injuries to the arm, especially fractures, should be impressed with the possibility of musculospiral development.

The Acute Abdominal Manifestations of Syphilis.—Dr. LOUIS A. LEVISON of Toledo in a paper on this subject summarized as follows: 1. Syphilis showing acute abdominal manifestations was not uncommon, but was not generally recognized. 2. The liver was the organ most often affected. 3. Abdominal manifestations occurred more often in the tertiary stage. 4. Syphilis of the stomach could simulate most of the ordinary gastric diseases. 5. The symptoms of acute abdominal manifestations of syphilis were in no way diagnostic and included pain, tenderness, fever, jaundice, chills, and sweats. 6. The gastric crises of tabes might be considered syphilitic in their nature.

The Wassermann Test.—Dr. W. T. MEFFORD of Chicago spoke on the value of this test to the physician. As to what class of patients he would recommend for a Wassermann test, he would say: all persons giving a history of syphilis, either inherited or acquired, and all persons with clinical symptoms simulating syphilis, and in late manifestations of syphilis. He would use it as he would a urinary or sputum examination, or blood count, placing the Wassermann test side by side with these as an assistance in making up the clinical findings. In all cases where he got a positive Wassermann or an active syphilis either alone or associated with other diseases, he would put the patient upon mercurial treatment. Of all conditions in which syphilis was associated, where he got the best results in treatment had been in syphilis associated with the heart and arterial system. Next the liver. He had not got the improvement in tuberculosis associated with syphilis that he expected or had hoped for by specific treatment, or the treatment of syphilis.

Pyloric Stenosis in the Infant.—Dr. W. D. HAINES of Cincinnati reported a case on which he had operated for the relief of this condition. The child was removed to a hospital and posterior no loop gastrojejunostomy was performed. Twenty-four hours after the operation the child showed no distress after taking nourishment and had continued free from his old symptoms. Except constipation, all of the symptoms had disappeared and though still undersized the child was thriving and playful five months after operation.

Pleural Effusions, Their Diagnosis and Treatment.—Dr. E. B. MONTGOMERY of Quincy, Ill., in this paper pointed out the importance of early diagnosis, and as a means of deciding doubtful cases, in addition to auscultation and percussion, needling, not only once, but repeatedly, if necessary. The use of sodium salicylate was advised as a medical treatment of small serous effusions, to be followed by aspiration if the fluid did not disappear in ten days or two weeks. For empyema the importance of a bacteriological diagnosis of the character of the infection was urged as a preliminary to correct treatment. Some pneumococcus empyemas yielded readily after aspiration to injection of two ounces of two per cent. formalin-glycerin. Others required intercostal incision and continuous drainage by one of the various types of drainage tubes, rib resection being rarely called for. To hasten the cure of small empyematous cavities and fistulæ, attention was called to the value of injections of Beck's thirty-three per cent. bismuth-vaselin paste.

Etiology of the Functional Neuroses.—Dr. ELEANORA S. EVERHARD AND DR. GERTRUDE FELKER of Dayton, Ohio, contributed a joint paper on this subject in which they drew the following conclusions: 1. That the common element in the attributed causes of the functional neuroses was to be found in the fact that the mental processes were not directed; therefore, the patient was the victim of any stimulus which chance might keep before the mind, and that there was no limit to the destruction of efficiency which might result. 2. That those symptoms commonly called nervousness were worthy of serious consideration because they indicated some degree of lack of control of nerve processes. 3. That self-indulgence by training the mind to follow the lines of least resistance predisposed to these neuroses. 4. That the value of living in accord with the laws of hygiene could not be overestimated, both because of its influence upon nutrition, and because it required a measure of self-control, but that alone was insufficient. 5. That conditions of life which demanded of

the individual in his vocation or avocation less exercise of attention and will than he was capable of enduring without fatigue bore to his nervous system the same relation that lack of muscular exercise bore to his muscular system. 6. That intelligent education at any age was effective, but since the ideal was prevention, the habit of directing mental processes should be established early.

Dr. Charles F. Read of Hospital, Ill., spoke of the psychic factors in the causation of certain functional psychoses, and presented clinical studies.

Dr. Liston H. Montgomery of Chicago read a paper in which he spoke of the rôle of the physician, philanthropist, publicist, and politician, regarding a federal department of health. He said that when a national department of health was established it would be capable of rendering the greatest amount of good to the greatest number of happy people, and thereby the prospects of longevity of man, ideal citizenship, and posterity would be greatly enhanced, for which the medical profession would stand as sponsor.

Standardization of Bacterins.—Dr. Roswell T. Pettit of Ottawa, Ill., spoke of the value of bacterin therapy as a general aid to local treatment in certain types of bacterial infections which was at the present time pretty well established. In the preparation of vaccines he did not try to estimate the number of bacteria present in a given volume. He took up a twenty-four hour blood agar growth of streptococci in a definite amount of salt solution, shook thoroughly, centrifuged to throw down the clumps, put in a bottle specially prepared and killed by heat or carbolic acid. Then he made a one-tenth of one-hundredth dilution of this full emulsion and gave an initial dose of five c.c. of the one-hundredth dilution. This induced very little or no reaction. The dosage was then increased up through the one-tenth dilution and full emulsion to the point of local reaction. Then he proceeded very slowly, keeping in mind that the reaction induced and results obtained were the true indices of dosage. The reaction to be aimed at was a slight or moderate local reaction, an area of redness about the size of a dollar, without the localizing or general phenomena. By using increasing doses up through a series of dilutions this could be procured with a fair degree of accuracy and an estimation of the number of bacteria used was entirely superfluous. The full emulsion could be called one hundred per cent. and ten per cent. and one per cent. dilution of this full emulsion made. The doses could be recorded as 1, 2, 5, 7 c.c., etc., of the one per cent., ten per cent., or one hundred per cent. emulsions. The advantages of a dilution method of estimating bacterial suspensions over a numerical were several. 1. The reaction, the real index of dosage, was relied upon and the empirical administration of bacterins was made less possible. 2. An index of antibody production was aimed at. 3. By using this method vaccines could be prepared with much greater rapidity, at least an hour was saved on each bacterin prepared, and if bacterins proved to be of value in acute infections—and the recent work of Dr. Rosenow of Chicago on artificial immunization in pneumonia seemed to point in this direction—the time saved would be a very important factor.

Dr. Nathan Rosewater of Cleveland read a paper in which he pointed out the non-operative treatment of the prolapsed and dilated stomach and abdominal viscera.

Treatment of Pernicious Anemia Associated with Achylia Gastrica.—Dr. Alfred C. Croftan of Chicago submitted a clinical report in regard to the treatment of a certain group of pernicious anemia cases and described three cases that had been improved rapidly and have remained symptomatically well, without remissions, until the present date. The one constant factor observed in the cases of pernicious anemia observed during a period of years that were not distinctly attributed to the effect of syphilis, carcinoma, parasites or profound and continuous loss of blood was a lack of hydrochloric acid from the stomach contents, associated with a variety of digestive disturbances, allied with varying degrees of chronic undernutrition. That all cases of hypochlorhydria and all cases of chronic undernutrition did not develop pernicious anemia called for the inclusion of some specific factor or factors, hitherto unknown. At all events, the supplying of large quantities of hydrochloric acid together with abundant proteids by mouth and by rectum seemed a favorable point of attack and was persistently carried through with gratifying results. The dosage, technique of proteid, overfeeding, and the general hospital management of such cases were described in full. From the results obtained the conclusion was drawn that a trial of this plan in this group of cases was decidedly worth while and seemed to produce results not otherwise attainable by any means so far described.

The Diagnosis of Trifacial Neuralgia.—Dr. Hugh T. Patrick of Chicago said in the vast majority of cases the diagnosis of the tic douloureux should be easy and certain as the traits of the disease were few and striking. But the author had had quite a number of other disorders referred to him as trifacial neuralgia. The most frequent had been migraine and sinus disease. Others were syphilis, brain tumor, alveolar abscess, and other dental disease, nasal disease, herpes zoster, neurasthenia and lesion of the optic thalamus. The pain of trifacial neuralgia was practically unique. There was nothing else just like it. It was short and sharp, in the beginning only a flash or jab, or shot. The interval might be anywhere from a second or two to weeks or months. In the fully developed disorder the paroxysms might last a minute or two and the free intervals be so short that the pain seemed continuous. It never really was so. Nearly every patient had intermissions of weeks,, months, or even years during which he was entirely free from pain. One of the most striking peculiarities of the affection was that the paroxysms or jabs of pain were started by slight peripheral irritation, such as washing the face, using a handkerchief, stroking the mustache or the touch of a glass to the lips. He thought that the automatic act of winking often acted as an excitant. Such slight sensory stimulus in the area of one division of the nerve might occasion pain in another division. For instance, touching the lower lip might start a pain not in this region, but in the supra-orbital area.

Water, the Main Factor in Prevention of Disease.—Dr. J. C. Minor of Hot Springs, Ark., said the significant points in his paper were: First, nutrition and elimination were the main factors in maintaining health; but of the two, elimination was absolutely necessary and must be continuous and invariably performed equally by the sewers of the body. One could not flush sewers without water, and if regular flushing was to be had the water must be furnished the body regularly, and the purer the better. Second, normal resisting power prevented invasion of any and all diseases. Normal resisting power depended upon normal distribution of food, normal lubrication of all body structures, and normal excretion of all waste products. Third, unless food were distributed to the system properly it would become a detriment instead of help to the system. It could not be distributed to the system properly without the proper amount of water taken in at the proper time. The stomach was the kitchen in which pabulum was prepared for the system. The small intestine was the table from which the system was served. The system would be served with only just enough, the remainder of the ingesta was thrown through the cecal valve into the sewer. If food was badly digested the system rejected it. If food was in greater amount than the system required the surplus was also rejected. All the

rejected food was an irritant to the cecal region and its continuity. Might it not be a cause for appendicitis? Fourth, there was a proper time for taking the proper amount of water. One's judgment should govern the measure of water to be taken with food. To take too much water just before, during, or just after a meal would be, so to speak, to put the fire in the kitchen out, while not enough fluid would compel the stomach to borrow too heavily from the systemic volume.

The Gradual Evolution of a Sane Therapy in Tuberculosis.—Dr. F. M. POTTENGER of Monrovia, Cal., contributed a paper on this subject. Among other things he said: The position of the sanatorium in the rational treatment of tuberculosis was very important. If the sanatorium was conducted on the proper lines it afforded the best circumstances under which the known measures, which had influence in building up and curing the patient, might be applied. The home treatment, however, was one of the greatest boons to tuberculous patients, because most patients were not able to be treated in sanatoria and must be treated in their own homes. The true position of home treatment, however, could be readily understood by the fact that it was an attempt to apply sanatorium régime and sanatorium conditions to the home.

Intestinal Surgery with a Demonstration of a New Method of Suturing the Bowel.—Dr. A. E. BENJAMIN of Minneapolis stated the various instruments and appliances formerly used to facilitate the surgeon in his work upon the intestines had about all been discarded for the simple, but efficient, method of intestinal anastomosis by thread and needle. The work should be carefully, but rapidly, performed, which was often the case where the surgeon had from practice or experimental work upon the lower animals become skillful in the use of needle and thread. A positive blood supply to the tissues making up the anastomosis was necessary. The end-to-end method was not so certain; therefore, the side-to-side anastomosis should be chosen when convenient. The evolution of the intestinal suture had brought them to the point where they were certain of good results, when the sutures were properly applied and were of the right material. Nonabsorbable suture material should be cast off into the lumen of the intestine after serving its period of usefulness, and this was best accomplished when used for the inner layer. There was then less destruction of tissue. When placed externally it produced unnecessary adhesions, plastic exudate and fibrous bands. It might interfere with proper bowel function, because of its prolonged irritation. Absorbable suture material used for the outer layer was soon taken care of and did not cripple the action of the intestine. The application of the suture in the intestinal work had been carefully studied. It must serve the purposes of controlling hemorrhage, proper coaptation of the tissues, security against leakage, must avoid pursing, be quickly introduced, and not strangulate the tissue. The back lock stitch of Pagenstecher's thread as applied by the author for the inner layer served all these purposes. Experimental work had demonstrated that chromic catgut lasted sufficiently long when employed as the outer suture for positive and firm union to occur. The after-treatment of cases of suturing the bowel should be carefully supervised by limiting the diet, starvation treatment, if necessary, until the union was sufficiently strong before it became necessary for the bowels to be called upon to pass their contents onward.

Officers.—The following officers were elected: *President*, Dr. Robt. H. Babcock, Chicago; *Vice-Presidents*, Drs. Arthur D. Holmes, Detroit, and Charles E. Barnett, Fort Wayne, Ind.; *Secretary*, Dr. Henry Enos Tuley, Louisville; *Treasurer*, Dr. S. C. Stanton, Chicago.

The selection of the place of meeting for 1911 was left to the Executive Committee with power to act.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS FOR THE STATE OF TEXAS.

Austin, June 28-30, 1910.

ANATOMY.

1. Give the origin, relation, course, and distribution of the posterior tibial artery.
2. Give the muscles of the orbital region, describing one, giving its attachments and insertion with its action and nerve supply.
3. Describe the posterior triangular space of neck, naming the structures found therein, together with their relation to each other.
4. Describe the ulna, giving its muscular attachments.
5. Describe knee joint, giving the osseous and ligamentous structures that enter into its formation.
6. Describe the collateral circulation around the elbow.
7. Describe the perineum, giving the nerve and blood supply to the parts, together with their source and relations.
8. Name the extensor group of muscles of the forearm; describe one fully, giving its attachment, and insertion, together with its action and nerve supply.
9. Describe the brachial plexus of nerves.
10. Outline and give a gross description of the liver, together with its relation to the internal organs.

HISTOLOGY.

1. Describe the histological structure of the skin.
2. Describe the histological structure of the pancreas.
3. Describe the histological structure of the tonsils.
4. Where is unstriped muscular tissue found?
5. Describe the Pacinian corpuscles.
6. Give the histological difference between the wall of an artery and the wall of a vein.
7. Name the genital organs of the male system and describe the vas deferens.
8. Name the genital organs of the female system and, if any, what is the difference between the mucosa of the body of the uterus and that of the cervix.
9. Enumerate the different epithelia, giving a locality or organ in which each is found, predominates.
10. Describe the microscopical appearance of a cross-section of a nerve fiber.

PHYSIOLOGY.

1. (*a*) Name the nerves supplying the tongue; (*b*) give the function of each.
2. Give the velocity of the blood flow (*a*) in the large arteries; (*b*) capillaries; (*c*) give time necessary for a complete circulation of the blood; (*d*) give velocity of nerve impulse.
3. To classify all the senses as external and internal; name five belonging to each class.
4. Give action and tell where found of the following enzymes: (*a*) amylopsin, (*b*) invertase, (*c*) lipase, (*d*) pepsin, (*e*) erepsin.
5. What tissues of the body possess marked power of contractility?
6. (*a*) Name the nerves supplying the heart, (*b*) give function of each.
7. What artificial stimuli may produce muscular contraction?
8. What is the normal blood pressure in an adult, expressed in millimeters?
9. Define the following terms: (*a*) tidal, (*b*) complemental, (*c*) supplemental, (*d*) residual air, and (*e*) vital capacity.
10. Define (*a*) miosis, (*b*) mydriasis, (*c*) eupnea, (*d*) necremia, (*e*) hydremia, (*f*) choluria, (*g*) biotomy, (*h*) albuminuria, (*i*) alopeceia, (*j*) chemosis.

CHEMISTRY.

1. Give (*a*) toxic symptoms of bismuth, (*b*) say how they may occur, (*c*) and describe a test for same.
2. Give (*a*) symptoms of fatal dose, and (*b*) treatment of ammonium hydroxide poisoning.
3. Give Graham's law covering diffusion of gases.
4. The presence of ammonia in excess of 0.05 mg. per liter in water indicates what?
5. (*a*) What is acetone, (*b*) clinical significance, (*c*) describe a practical test for same.
5. Define hemoglobinuria and give a test for hemoglobin.
7. Give a simple, practical test for pus in the urine.

8. (*a*) What is muscarin, (*b*) where found, (*c*) symptoms of poisoning, (*d*) antidote?
9. How is the specific gravity of a gas determined?
10. Differentiate dialysis and osmosis.

BACTERIOLOGY.

1. Describe the Gram's method of staining.
2. Name three pathogenic bacteria that are stained by the Gram's method.
3. Name or give examples of three different bacteria which do not stain readily.
4. Describe the process of staining blood.
5. In normal blood, stained, describe the various cells.
6. Name three different pus producing bacteria.
7. What are the chief effects of bacterial growth?
8. Before being accepted as the cause of a given disease a germ must conform to what is known as "Koch's four laws"; name them.
9. In diagnosis, name the means for identifying bacteria.
10. What are ptomaines and toxins?

PHYSICAL DIAGNOSIS.

1. Give the physical signs of Raynaud's disease and describe the different grades.
2. What is meant by dyspnea; in what disease is it a prominent symptom?
3. Name six causes for the displacement of the cardiac apex.
4. Name the points to be noted when taking the pulse.
5. Give the most important signs of thoracic aneurysm.
6. Name the different groups of emphysema; and describe each briefly.
7. What organs can be felt through the abdominal walls by palpitation?
8. Name the most common diseases affecting the peritoneum, and the commonest cause of local peritonitis.
9. What is meant by jaundice, and give some of the causes?
10. Name some of the symptoms of intestinal diseases.

PATHOLOGY.

1. Panaritium tendinæum: Give its pathology and give reason why a felon of the thumb and little finger is more liable to spread into the palm of the hand than felon of the three middle fingers.
2. Wounds: In a wound of any kind, septic or aseptic, certain principles of treatent if faithfully carried out will greatly contribute toward a union by first intention; please name these principles.
3. Poisons: Caustics and irritants—describe their effects upon the body tissues and how these effects are brought about.
4. Give causes of catarrhal jaundice, and its effects upon the system.
5. Give pathology of pleurisy and name the two diseases it most commonly occurs in as a complication.
6. Give pathology of phlegmonous tonsillitis.
7. Give pathology of yellow atrophy of the liver.
8. Name three varieties of sarcoma, and describe the cells of each variety named.
9. Typhoid fever: Give its cause and pathology.
10. Dermoid cysts: To what class of tumors do they belong, and on what parts of the body do they most frequently occur?

OBSTETRICS.

1. Describe the human embryo during the fourth, sixth and eighth month, giving the appearance and weight.
2. What effect would double ovariotomy have on the fetus of five months' gestation?
3. Describe changes occurring in the blood during gestation.
4. What are the effects of an acute zymotic disease during pregnancy on (*a*) mother, (*b*) child?
5. What are the dangers to (*a*) mother, (*b*) the child, from gonorrhea during pregnancy and labor?
6. What is the significance of glycosuria during pregnancy, and the frequency of its occurrence during pregnancy?
7. Causes, pathology, and treatment of puerperal eclampsia and the danger signs of impending eclampsia?
8. Give the varieties of puerperal eclampsia and their differential diagnosis.
9. What is Tarnier's sign of inevitable abortion, and give its importance in the diagnosis of inevitable abortion?
10. Give formation of caput succedaneum and where does the caput succedaneum appear in the third position?

GYNECOLOGY.

1. Give clinical symptoms of stenosis of the cervix, and give remedy.
2. Give differential clinical diagnosis of cervical stenosis and atresia of the vagina.
3. Give the classification and causes of dysmenorrhea.
4. Give the causes of and remedy for procidentia.
5. Give differential diagnosis of ovaritis and appendicitis in a young woman; would you or would you not advise operative procedure in either condition?
6. For what pathological condition would you advise amputation of the cervix?
7. What are the relations between menstruation and ovulation?
8. Give the hygiene of the menstrual period.
9. What is artificial menopause, its etiology and the pathological conditions that justify it?
10. When and for what purpose would you use the following suture material: silk, silkworm gut, plain catgut, chromic catgut and silver wire, in gynecological work?

SURGERY.

1. How do you prepare patients for the administration of anesthetics?
2. How do you treat acute synovitis?
3. How is the callus disposed about a fracture?
4. What are the causes of gangrene?
5. What complications accompany fractured ribs?
6. What symptoms denote malignant disease of the prostate?
7. What changes take place in strangulated hernia?
8. What precautions are observed in excising a joint?
9. Under what circumstances should the head of the femur be excised?
10. Give differential diagnosis between intracapsular fracture and an extracapsular.

HYGIENE.

1. Why and how is carbon dioxide deleterious to health?
2. Name the chemical germicides most commonly used and the proportions employed?
3. What is the difference between fermentation, oxidation, and putrefaction?
4. Mention the preventable epidemic diseases, and state how you would stop the spread of each.
5. Name and describe the principal chemical elements of food, giving the use of each?
6. ...at is the effect of alcohol upon the nerve centers; circulation?
7. How are impurities in water classified; how can they be detected, and why is the presence of organic material in drinking water deleterious?
8. Give the principal factors upon which natural and acquired immunity depend?
9. Give period of detention of persons exposed to the following infectious diseases: Smallpox, measles, scarlet fever, diphtheria, cholera, typhoid fever, and yellow fever?
10. Give the formation of the four standard disinfecting solutions.

MEDICAL JURISPRUDENCE.

1. Give the eight varieties and classification of insanity.
2. What is meant by justifiable abortion; (*b*) and differentiate justifiable abortion from criminal abortion.
3. Give the chemical tests of blood.
4. (*a*) What is meant by rape; (*b*) give the three important constant symptoms or signs as medical testimony in alleged rape?
5. What do you understand by age of consent in reference to rape?
6. Give common cause of death from wounds.
7. Describe death from and give the post-mortem signs of strangulation.
8. Describe, define, and differentiate illusion, delusion, and hallucination, and the lucid interval.
9. What are the effects of exposure to extreme heat?
10. By what means may the dead be identified?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS FOR THE STATE OF TEXAS.

Austin, June 28-30, 1910.

ANATOMY.

1. The *posterior tibial artery* is the continuation downward of the popliteal artery. It begins at the lower border of the popliteus muscle; it ends midway between the internal malleolus and the tuberosity of the os calcis, where it divides into the external and internal plantar arteries. Its *branches* are: Peroneal, nutrient, muscular, cutaneous,

communicating, internal calcanean, and malleolar cutaneous. *Relationships. In front:* Tibialis posticus, flexor longus digitorum, tibia, and ankle joint. *Behind:* Skin, fascia, gastrocnemius, soleus, posterior tibial nerve, and abductor hallucis. *On inner side:* Posterior tibial nerve, at upper part. *On outer side:* Posterior tibial nerve, at lower part.

2. See Cunningham's "Anatomy" (1909), page 399; or Gray's "Anatomy" (1908), page 374.

3. See Gray's "Anatomy" (1908), page 620.

4. See Cunningham's "Anatomy" (1909), page 194; or Gray's "Anatomy" (1908), page 186.

5. See Cunningham's "Anatomy" (1909), page 297; or Gray's "Anatomy" (1908), page 336.

6. The vessels anastomosing *in front of the internal condyle* are: Anastomotica magna, anterior ulnar recurrent, and anterior terminal branch of inferior profunda; *behind the internal condyle:* Anastomotica magna, posterior ulnar recurrent, and posterior terminal branch of inferior profunda; *in front of external condyle:* Radial recurrent and anterior terminal branch of superior profunda; *behind external condyle:* Anastomotica magna, interosseous recurrent, and posterior terminal branch of superior profunda.

7. See Cunningham's "Anatomy" (1909), page 1277; or Gray's "Anatomy" (1908), page 1549.

8. See Cunningham's "Anatomy" (1909), page 348; or Gray's "Anatomy" (1908), page 486.

9. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius. The *branches* are: (1) Above the clavicle; communicating, muscular, posterior thoracic, and suprascapular. (2) *From outer cord:* External anterior thoracic, musculocutaneous, and outer head of median. (3) *From inner cord:* Internal anterior thoracic, lesser internal cutaneous, ulnar, and inner head of median. (4) *From posterior cord:* Subscapular, circumflex, and musculospiral.

10. See Cunningham's "Anatomy" (1909), page 1108; or Gray's "Anatomy" (1908), page 1334.

HISTOLOGY.

1. See Cunningham's "Anatomy" (1909), page 772; or Gray's "Anatomy" (1908), page 1190.

2. See Gray's "Anatomy" (1908), page 1359.

See Gray's "Anatomy" (1908), page 1223.

4. *Unstriped muscular tissue* is found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, within the eyeball, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs.

5. See Cunningham's "Anatomy" (1909), page 775; or Gray's "Anatomy" (1908), page 830.

6. See Cunningham's "Anatomy" (1909), page 781; or Gray's "Anatomy" (1908), pages 586 and 722.

7. See Cunningham's "Anatomy" (1909), pages 1159 and 1162; or Gray's "Anatomy" (1908), pages 1457 and 1484.

8. See Cunningham's "Anatomy" (1909), pages 1181 and 1191; or Gray's "Anatomy" (1908), pages 1489 and 1504.

9. KINDS OF EPITHELIUM. (1) *Pavement* or *Squamous:* A single layer of flat, nucleated cells, cemented together at their edges; found in descending limb of Henle's loop. (2) *Stratified squamous:* In layers of cells that are unlike in form; found in the epidermis. (3) *Columnar:* Tall, cylindrical cells arranged in a single layer; found in penile part of urethra. (4) *Cuboidal:* Similar to columnar, but the cells are shorter; found in thyroid gland. (5) *Ciliated:* Columnar cells with hair-like processes (cilia) on their free surface; found in Fallopian tubes. (6) *Transitional:* When the cells are neither arranged in a single layer like squamous, nor yet in many superimposed layers like stratified, but in two or three layers; found in pelvis of ureter.

10. See Gray's "Anatomy" (1908), page 825.

PHYSIOLOGY.

1. *Nerve supply of tongue:* (1) Hypoglossal, to muscles —the motor nerve; (2) Chorda tympani, nerve of taste to the anterior two-thirds; (3) glossopharyngeal, nerve of taste and also of general sensation to the posterior two-thirds; (4) Lingual (or Gustatory), nerve of sensation to anterior two-thirds.

2. (*a*) In large arteries, about a foot a second; (*b*) in capillaries, about an inch a minute; (*c*) complete circulation time, about 23 seconds; (*d*) velocity of nerve impulse: motor impulses, about 33 meters a second; sensory impulses, about 30 to 33 meters a second.

3. *External senses:* Sight, hearing, taste, smell, pressure, and temperature (heat and cold). *Internal senses:* Pain, muscular sense, the sensations from the semicircular canals and vestibule of the internal ear, hunger, thirst, sexual sense, and fatigue.

4. (*a*) *Amylopsin* is found in the pancreatic juice; it converts starches into maltose. (*b*) *Invertase* is found in the succus entericus; it converts maltose into glucose. (*c*) *Lipase* is found in the pancreatic juice; it emulsifies and saponifies fats. (*d*) *Pepsin* is found in the gastric juice; it changes proteids into proteoses and peptones in an acid medium. (*e*) *Erepsin* is found in succus entericus; it breaks up albumoses, peptones, casein, and changes them into leucin, tyrosin, and ammonia.

5. Muscles; also protoplasm, and the cilia of ciliated epithelium.

6. The *nerves which control the heart* are: (1) The pneumogastric nerve, which slows or inhibits the heart-beats; (2) the sympathetic nerves, which accelerate or augment the beats; and (3) the intrinsic cardiac ganglia, which enable the heart to continue beating for some time after it is removed from the body.

7. Muscular contraction may be produced by: Mechanical, chemical, thermic, and electric stimuli.

8. The normal arterial blood pressure varies; the systolic pressure being about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury.

9. *Tidal air* is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches.

Complemental air is the air which can be taken in beyond what is normally inspired in ordinary breathing. It measures about 100 cubic inches.

Supplemental air is the air which can be expelled at an extraordinary expiration. It measures about 100 cubic inches.

Residual air is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

Vital capacity is the amount of air which can be expelled from the lungs by an extraordinary expiration after the most forcible inspiration. It includes the tidal, complemental, and reserve air, and measures about 225 to 230 cubic inches.

10. *Miosis* is a diminution in size of the pupil. *Mydriasis* is dilatation of the pupil. *Eupnea* is normal or easy respiration. *Necremia* is a loss of vitality of the blood. *Hydremia* is a watery condition of the blood. *Choluria* is a condition of bile in the urine. *Biotomy* is vivisection. *Albuminuria* is albumin in the urine. *Alopecia* is baldness. *Chemosis* is swelling and edema of the ocular conjunctiva.

CHEMISTRY.

1. The toxic symptoms of *bismuth* are generally attributed to contamination with arsenic or other impurity. "The *symptoms* observed are stomatitis, metallic taste, tenderness of the gums, dark discoloration of the tongue, diarrhea, pigmentation, and ulceration of the intestinal tract, especially the large bowel. The urine contains albumin and casts and occasionally a dark precipitate or a white precipitate, becoming dark on standing."—(Riley's *Toxicology.*) *Test:* Solutions suspected of containing *bismuth* may be examined by the *Reinsch's test,* as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If bismuth is present no mirror will be formed in the tube.

2. AMMONIUM HYDROXIDE POISONING. *Symptoms:* "When a solution is swallowed the symptoms depend on the state of concentration. A sufficient quantity of the gas escapes from the stronger solutions during the act of swallowing to endanger the lungs or cause death by suffocation. A large dose may cause death almost as quickly as hydrocyanic acid by inducing spasm of the glottis, or shock, by its intense irritation of the stomach. When the dose is not so large or is less concentrated there is immediate severe pain in the mouth and throat, soon extending to the stomach, vomiting of soapy mucus, intense pain and tenderness of the abdomen, aphonia, frequently accom-

panied by profuse salivation. The glands under the jaw and the lymphatics of the neck frequently become swollen and tender. Secondary results, including chronic laryngitis, edema of the glottis, stricture of the esophagus, etc., are apt to follow recovery from the acute effects of the poison, but they do not follow so uniformly, nor are they generally so severe as those following poisoning by the fixed alkalies. *Treatment:* Do not use the stomach pump. Give the mild vegetable acids, dilute vinegar, lemon or lime juice, orange juice, dilute solutions of citric or tartaric acids, cream of tartar, etc. Vegetable or animal oils, milk, cream, and demulcent drinks may be given in the absence of the acids or following their administration. The dilute mineral acids may be given if due caution is used to have them sufficiently dilute and not to give them in excess."—(Kiley's *Toxicology.*)

3. *Graham's law of diffusion of gases:* The rates of diffusion of two gases into each other are in the inverse ratio of the square roots of their densities.

4. It indicates (probably) organic matter of animal origin, sewage.

5. ACETONE is dimethyl ketone. *Clinical significance:* It is found in normal individuals, particularly stout persons, with deprivation of food, in febrile diseases when the febrile condition is prolonged, in certain mental diseases, such as general paresis, melancholia, and epilepsy, after chloroform narcosis, in puerperal eclampsia, and in diabetes. *Test:* Add a few drops of a freshly prepared solution of sodium nitroprussid, and then KHO or NaHO solution, when, in the presence of acetone, the liquid is colored ruby-red, and, on supersaturation with acetic acid, changes to purple.

6. HEMOGLOBINURIA is the presence of hemoglobin in the urine. *Test:* To a few drops of urine in a test tube add one drop of a freshly prepared tincture of guaiacum and a little ozonic ether, and shake; a blue color is produced if hemoglobin is present.

7. *Test for pus in urine:* Add an equal quantity of potassium hydroxide to the suspected urine; if pus is present a viscid gelatinous mass will be formed.

8. *Muscarin* is an alkaloid found in the Agaricus muscarius, and during the putrefactive decomposition of proteins. It is a monamin. "When administered to animals, muscarin causes increased secretion of saliva and tears; vomiting; evacuation of feces, at first solid, later liquid; contraction of the pupils, almost to the extent of closure; diminution of the rapidity of the pulse; interference with respiration and locomotion; gradual sinking of the heart's action and respiration; and death. Atropin prevents the action of muscarin and diminishes its intensity when already established."—(Witthaus' *Manual of Chemistry.*)

9. The specific gravity of a gas can be determined by dividing its molecular weight by that of the gas taken as a unit.

10. *Dialysis* is the process of separating substances from each other by placing the mixture containing them in a vessel with porous walls and immersing it in water, when the more diffusible substances pass through the walls.

Osmosis is this passage of a liquid or of substances in solution through a porous membrane.

BACTERIOLOGY.

1. *Gram's method of staining:* Stain a cover glass preparation for two or three minutes in anilin gentian-violet. Wash in water. Treat with Gram's solution (iodine, 1 gram; potassium iodide, 2 grams; water, 300 c.c.) for a minute and a half, when the preparation becomes nearly black. Decolorize with strong or absolute alcohol for at least five minutes, wash, dry, and mount. Sometimes a contrast stain of Bismarck brown or eosin is used.

2. *Gram-positive: Tubercle bacillus, Klebs-Loeffler bacillus, Tetanus bacillus.*

3. *Gram-negative: Bacillus typhosus, Bacillus coli communis, Spirillum of Asiatic cholera.*

4 and 5. See French's "Practice of Medicine" (1907), page 1176.

6. *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus,* and *Streptococcus pyogenes.*

7. *Chief effects of bacterial growth* are: Colors, odors, light, ferments, putrefaction, toxins, diseases, acids, alkalies, indol, liquefaction of gelatin nitrates, and phosphorescence.

8. Koch's four laws in regard to the bacterial cause of disease are: (1) The microorganism must be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

9. By cultural characteristics, staining properties, morphology, and animal inoculation.

10. *Ptomaines* are the putrefactive products of dead animal tissues or fluids.

Toxins are the poisonous products of pathogenic bacteria or of ptomaines or leucomaines.

PHYSICAL DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), page 1159; or Osler's "Practice of Medicine" (1909), page 1100.

2. *Dyspnea* is breathing that is painful, or difficult, or laborious. It is a prominent symptom in pneumonia or asthma.

3. *Six causes of displacement of cardiac apex:* Pericardial effusion, cardiac hypertrophy, cardiac dilatation, mediastinal tumor, enlarged liver, and pleural effusions.

4. In taking the pulse note: The force, frequency, rhythm, tension, amplitude, duration, the condition of the artery.

5. See French's "Practice of Medicine" (1907), page 630; or Osler's "Practice of Medicine" (1909), page 857.

6. See French's "Practice of Medicine" (1907), page 679; or Osler's "Practice of Medicine" (1909), page 633.

7. Stomach, small intestine, large intestines, liver, gallbladder, spleen, kidneys, uterus.

8. See French's "Practice of Medicine" (1907), page 863; or Osler's "Practice of Medicine" (1909), page 580.

9. See French's "Practice of Medicine" (1907), page 842; or Osler's "Practice of Medicine" (1909), page 534.

10. *Some of the symptoms of intestinal disease:* Pain; tenderness; diarrhea; constipation; flatulence; colic; fever; furred tongue; anorexia; scanty urine; nausea; vomiting; the stools may be abnormal in color, odor, quantity, or consistency, or may contain blood, pus, or other abnormal material; tenesmus.

PATHOLOGY.

1. See Rose and Carless' "Surgery" (1908), page 247; or Da Costa's "Surgery" (1908), page 648.

2. See Rose and Carless' "Surgery" (1908), page 231; or Da Costa's "Surgery" (1908), page 244.

3. *Caustics and irritants* "exercise a destructive effect upon the cells with which they come in contact, partly by abstraction of water and partly as result of a coagulating power or similar action. The acids and mineral caustics usually produce dry and more or less discolored areas of necrosis; the caustic alkalies cause a sort of gelatinous change or a saponification of the tissue. The degree of injury depends upon the poison and the amount in contact with the tissues. There may be only a superficial injury of the outer layer of epithelial cells, or extensive destruction. Reactive inflammation is almost always present, and often, especially in the mucous membranes, the inflammatory reaction is extensive, though the corrosive action of the poison is limited in depth and extent. The affected part may present slight areas of necrosis with reactive hyperemia and inflammation beneath and around them, or deep eschars, vesicles, or large bullæ. In the process of healing extensive scars may form, and these may be serious in their effects, as in the case of strictures of the esophagus."—(Stengel's *Pathology.*)

4. See French's "Practice of Medicine" (1907), page 842; or Osler's "Practice of Medicine" (1909), page 534.

5. See French's "Practice of Medicine" (1907), pages 690, 691, and 695; or Osler's "Practice of Medicine" (1909), pages 643, 645, and 649.

6. See French's "Practice of Medicine" (1907), page 719; or Osler's "Practice of Medicine" (1909), page 445.

7. See French's "Practice of Medicine" (1907), page 821; or Osler's "Practice of Medicine" (1909), page 539.

8. See Rose and Carless' "Surgery" (1908), page 190; or Da Costa's "Surgery" (1908), page 320.

9. See French's "Practice of Medicine" (1907), pages 65 and 70; or Osler's "Practice of Medicine" (1909), pages 57 and 65.

10. *Dermoid cysts* belong to the class teratomata. They most frequently occur in the ovary, orbitonasal cleft, angle of orbit, neck, eyelids, coccyx, floor of mouth, testicle, brain, eye, mediastinum.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 146; or Hirst's "Obstetrics" (1909), page 85.

2. See Hirst's "Obstetrics" (1909), page 549.

3. See Williams' "Obstetrics" (1909), page 172; or Hirst's "Obstetrics" (1909), page 185.

4 See Williams' "Obstetrics" (1909), page 480.

5. See Williams' "Obstetrics" (1909), pages 483 and 854; or Hirst's "Obstetrics" (1909), pages 227 and 727.

6. See Williams' "Obstetrics" (1909), page 493; or Hirst's "Obstetrics" (1909), page 253.

7. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral; (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

The danger signals of impending eclampsia are: Headache; tinnitus aurium; dizziness; pain over stomach; digestive, visual, and nervous disturbances; general debility; insomnia, vomiting, and vertigo.

8. See Williams' "Obstetrics" (1909), pages 517, 518, 524, and 540; or Hirst's Obstetrics" (1909), pages 628 and 632.

9. See Hirst's "Obstetrics" (1909), page 277.

10. See William's "Obstetrics" (1909), page 271.

GYNECOLOGY.

1. Stenosis of Cervix. *Symptoms:* Pain during menstrual period, increase in size of uterus, and retention of menstrual (and other) secretions; this latter may extend to the Fallopian tubes. *Remedy:* Find, and dilate the canal, pack with iodoform gauze, and keep patent by occasionally dilating.

2. In *cervical stenosis*, the vagina is patent, the os and cervix can be seen, and the symptoms are as above (Question 1.). In *atresia of the vagina*, there is destruction or adhesion of the vagina, so that the os and cervix can not be seen. There is amenorrhea, recurrent pains at the menstrual period, with bulging at the perineum, and inability for coitus.

3. *Dysmenorrhea is classified* as: Congestive, ovarian, membranous, obstructive and neuralgic. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus.

4. Causes of downward displacements of the uterus: (1) *Pressure from above* (pelvic or abdominal tumors, ascites, tight or heavy clothing, straining at stool, muscular exertion, fecal accumulations, habitual overdistention of the bladder); (2) *weakening and relaxation of the uterine supports* (subinvolution, senile atrophy of pelvic floor, abnormally large pelvis, increased weight of uterus, puerperal traumatisms, pressure from above, traction from below); (3) *increased weight of uterus* (congestion, subinvolution, metritis, pregnancy, fluid in the endometrium, uterine tumors); (4) *traction from below* (vaginal cicatrices, falling of pelvic floor, contraction and congenital shortening of vagina, tumors of cervix or vagina).—(From Dudley's *Gynecology.*)

Treatment: "Operative, unless some contraindication to operation exists. In such a case some *mechanic device* should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by Braun's colpeurynter. This is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter well anointed with carbolized vaseline and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations. *Operative treatment* gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the perineum will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina. The best of these is Martin's operation for cystocele. If the cervix is hypertrophied it should be amputated. Three operations—on the perineum, for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hystrorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, hysterectomy may be performed."

5. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender. Operation would be advised if indicated.

6. Hypertrophied and badly lacerated cervix.

7. The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

8. *Hygiene of the menstrual period:* "The care of women during the menstrual period is based upon common-sense principles and the general laws of hygiene. During the first twenty-four hours of the flow the pelvic organs are intensely congested, and it is therefore advisable for a woman to remain in her room in bed or lying on a sofa. Her duties subsequently should be as light as possible, and while the flow lasts all forms of active exercise, such as long walks, riding, or cycling, should be forbidden. Cold bathing in any form should be avoided, as it tends to check the flow and brings about chronic congestive conditions of the pelvic organs. For the same reason exposure to the inclemencies of the weather and sitting in drafts should be carefully guarded against. The laws of cleanliness should be strictly enforced and the body kept clean and the skin active by a general sponge bath of tepid water and soap. The external organs should also be cleaned twice or thrice daily with tepid water and soap, as the discharges are apt to become rancid and offensive, especially in warm weather. The napkins should be changed frequently and not allowed to become over-saturated and foul. Vaginal injections should not be employed while the flow continues unless ordered by a physician for therapeutic reasons. Sexual intercourse should also be avoided, as the congestion of the pelvic organs is increased by the act of copulation, and it may result in chronic inflammation or the formation of a pelvic hematocele. The diet during menstruation should be simple and easily digested, and all varieties of spiced or highly-seasoned foods should be interdicted. Alcoholic stimulants are also injurious, as they tend to prolong the flow and increase the pelvic congestion."—(Ashton's *Gynecology.*)

9. *Artificial menopause* is the menopause prematurely induced by removal of the ovaries. This is done for tubo-ovarian abscess, pyosalpinx, tubercular salpingitis, diseases of the ovaries.

10. Sutures in gynecological work: *Silk:* For skin, intestinal work, shortening round ligaments, shortening uterosacral ligaments, ventral fixation, or ventral suspension, urethral, and ureteral and bladder work and rectal work. *Silk worm gut:* Skin (through and through and subcuticular), fascia (buried and temporary), perineum, anterior wall and cervix (temporary sutures); ventral fixation (buried and temporary sutures). *Plain catgut:* Skin, fascia, peritoneum, broad ligaments, ovary, tube, bladder, rectum, perineum, anterior wall, muscle, fat. *Chromic catgut:* Same as plain catgut, but especially in fascia, cervix and anterior wall. *Silver wire:* Vesico-vaginal fistulæ, cervix, perineum, anterior wall, fascia, subcuticular.

SURGERY.

INTRACAPSULAR FRACTURE OF FEMUR.	EXTRACAPSULAR FRACTURE OF FEMUR.
1. CAUSE—Indirect violence, therefore little local injury.	1. CAUSE—Direct violence, therefore marked bruising over trochanter.
2. Crepitus usual.	2. Crepitus frequently absent.
3. No absolute loss of power.	3. Marked loss of power.
4. Shortening slight, may increase later, through atrophy of the neck.	4. Shortening greater, 1½ to 2 inches.
5. Trochanter usually of normal shape and size.	5. Trochanter thickened owing to impaction and formation of callus.

(*Essentials of Surgery.*)

HYGIENE.

1. Carbon dioxide is irrespirable, and suffocates; it is not a poison in the strict meaning of the term. Ordinarily carbon dioxide is injurious by diminishing the amount of oxygen.

2. *Chemical germicides:* Corrosive sublimate 1:5,000 to 1:1,000; carbolic acid, 1:40 to 1:20; creolin, 1 to 5 per cent.; formaldehyde, 40 per cent.; lysol, 1 to 3 per cent.; chloride of lime, 1:100.

3. *Fermentation* is a chemical transformation of *carbohydrates* as the result of the activity of microorganisms.

Putrefaction is the decomposition of dead *protein* matter as the result of the activity of certain microorganisms.

Oxidation is the act of union of oxygen with another element or compound.

4. Probably all the epidemic diseases are preventable; certainly smallpox, typhoid, diphtheria, malaria, and yellow fever can be prevented. The spread of any epidemic can be prevented by proper isolation, quarantine, and hygiene; and by the use of special precautions such as vaccination (for smallpox), immunizing doses of antitoxin (in diphtheria), keeping out or destroying mosquitos (in malaria and yellow fever), etc.

5. The *alimentary principles of food,* are:

I. Inorganic { Water. / Salts.

II. Organic { Nitrogenous—Proteids. / Non-nitrogenous. { Carbohydrates. / Fats.

The *function* (and constituents) are shown in the following table, adapted from Notter and Firth's *Hygiene:*

FOOD.	FUNCTIONS.
Proteids.	
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	These perform the above functions less perfectly, or only under particular circumstances.
3. Extractive matters, such as are contained in the juice of the flesh.	These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.
Carbohydrates.	
Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H_2O.	Production of energy and animal heat by oxidation. Form fats and possibly some proteids.
Fats.	
Substances containing no N, but made up of C, H and O; the proportion of O being *less* than sufficient to convert all the H into H_2O.	Supply of fatty tissues, nutrition of nervous system; supply of energy, and animal heat by oxidation.
Salts.	Support of bony skeleton, supply of HCl for digestion, regulation of energy and nutrition.

6. On the *nerve centers,* alcohol is first a powerful excitant, afterwards a depressant; it increases reflex activity and in large doses produces lack of coordination. On the *circulation,* it causes a rise of arterial pressure, and increases the rapidity and force of the heart.

7. *Impurities in water* are *classified,* as: Mineral, vegetable, or animal. They can be detected by chemical analysis, physical tests, and bacteriological examination. The presence of organic material in drinking water may denote sewage and disease germs.

8. See French's "Practice of Medicine" (1907), page 60.
9. See French's or Osler's "Practice of Medicine," in index, under head of these diseases.
10. See above, No. 2.

MEDICAL JURISPRUDENCE.

1. Melancholia, mania, idiocy, imbecility, monomania, general paralysis of insane, dementia, certain forms of mania with distinct etiological relations.

2. Abortion is the premature expulsion of the product of conception (at any period of gestation), whether ovum, embryo, or fetus. It is *justifiable* and not criminal when it is due to natural causes, or when done by a physician, after proper consultation, for sufficient cause. The chief conditions that justify the induction of abortion are: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. But when performed, or attempted, for any other reason, or under any other condition, it is *criminal.*

3. *Chemical tests for blood:* "(1) The red coloring matter of the blood dissolves readily in cold water. The color of this solution is not changed to crimson, but to green, by the addition of a few parts of a weak ammoniacal solution. (2) If a strong solution of ammonia be used, the red liquid will become somewhat brownish. (3) If this red solution be boiled, it becomes coagulated and the color a dirty brown, which settles out of the solution, leaving the water above. (4) Blood in any amount reacts always to the various albumin tests. (5) When a freshly prepared tincture of guaiacum is added to the original solution there is a reddish white precipitate. If to this is added an ethereal solution of peroxide of hydrogen, the color is changed to blue." (Dwight's *Jurisprudence.*)

4. *Rape* is carnal knowledge of a female by a man, unlawfully, forcibly, and without her free consent.

The *medical evidence* is based on: (1) Marks of violence about the woman's genital organs; (2) wounds, bruises, or other marks of injury on the woman or on the accused; (3) blood stains and seminal stains on the person or clothing of either party; and (4) the presence of any venereal disease on either party.

5. *Age of consent* is the age below which a female is incapable of giving legal consent to sexual connection, and such connection on the part of a man is rape, in spite of her consent or desire.

6. *The common causes of death from wounds* are: Hemorrhage, infection, shock, direct injury to a vital organ.

7. "*Strangulation* produces death by asphyxia together with pressure upon the great vessels, especially the jugular vein. As the result of pressure upon the vein, there are created a congestion of the vessels of the brain and a certain amount of interference with the heart's action." (Dwight's *Jurisprudence.*)

In *death by strangulation:* The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty, or nearly so. The lungs may be con-

gested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia.—(From Quain's *Dictionary of Medicine*.)

8. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

A *lucid interval* (in insanity) is a period in which there is a temporary cessation of the insanity, or a complete restoration to reason.

9. *Effects of extreme heat*, are: "Unconsciousness, dry skin, rapid or stertorous respiration, pulse usually rapid; if the temperature is high, it may run up to 112° F., and if it persists death follows within a short time. These signs may vary and simulate death from cerebral hemorrhage. When the individual recovers, it may be followed by delirium, and cases have been reported in which insanity was the result. Persistent headache is a fairly constant sequel, and the person affected is usually more susceptible to heat than was the case previous to exposure." (Dwight's *Jurisprudence*.)

10. *Identification of the dead* is based on: Deformities, tattoo marks, scars, general appearance, apparent age, figure, size, dress, moles, birthmarks, professional stigmata, examination of hair, condition of the teeth, color of hair and eyes.

PRACTICAL POINTS IN THE MANAGEMENT OF POLIOMYELITIS AND ITS SEQUELÆ.*

By HENRY LING TAYLOR, M. D.,

NEW YORK.

Acute poliomyelitis, or infantile spinal paralysis, occurs in epidemics and also sporadically in most of the civilized countries of the world. Recent extensive epidemics in New York, Massachusetts, Wisconsin, Nebraska, Scandinavia, and Germany have drawn renewed attention to its frequent occurrence, wide distribution, and disastrous consequences. It is predominantly a disease of midsummer and early autumn, and of the first years of childhood. In the New York epidemic of 1907 over 60 per cent. of the cases occurred before the fourth birthday, and over 90 per cent. before the sixth. It is, however, much more common in adolescents and adults than is usually supposed. In a group of four cases occurring in Southampton, N. Y., in the autumn of 1908, the ages were infancy, 13, 19, and 40 years, respectively. Many of the adult cases have passed under the title of Landry's paralysis, or under other designations. A recent case in a youth of 18 was diagnosed as typhoid fever, and the subsequent weakness, lameness, and wasting in the right leg were explained as a complicating neuritis. Numbers of cases of scoliosis in young adults have been traced to a previous attack of poliomyelitis, which in some instances left no permanent limb palsy, as in the case of a woman of 19 who had an attack of fever and weakness in the limbs, followed by lameness, which passed off entirely. Two years later there was a severe scoliosis with partial palsy of the back and abdominal muscles, for which she sought advice.

The negro race in America seems to be less susceptible than the white. Further study is needed as to the geographical and racial distribution of poliomyeltis. An investigation of its occurrence and communicability has been undertaken by the Massachusetts Board of Health since 1907, and it is to be hoped that New Jersey and other States will join in a systematic statistical study.

Poliomyelitis attacks all classes, the healthy as frequently as the delicate. It often occurs during teething, also after over-heating or over-exertion, especially if followed by a sudden wetting or chilling. It also not infrequently follows within a few hours or days after a definite moderate trauma, such as a blow or a fall.

In epidemics, two or more cases in a family or house have occasionally occurred, but in the New York epidemic of 1907 700 houses were reported with one case in each, and only 23 with two (18) or three (5). The disease has been communicated to monkeys and from monkey to monkey for several generations, by Flexner and others, and the virus has been found to be filtrable and ultra-microscopic. The writer has never observed a second attack in the same individual.

It has been definitely shown by Strauss and others that an extensive small cell infiltration surrounds the vessels of the infected area; that the cord is edematous; that the motor cells atrophy secondarily; that the pia of the spine, bulb, and base of the brain are regularly involved, even in those cases showing no cerebral, bulbar, or meningeal symptoms.

Fig. 1.—No. 1 of table; age 18; two years after attack; paralysis left side abdomen; legs somewhat affected, but walks well; scoliosis.

The onset is sudden, usually with fever and constitutional symptoms for a few hours or days, and the palsy follows in a short time. Prostration and inability to walk for a considerable time are common. It is now recognized that bulbar, cerebral, facial, neck, and trunk palsies are not very rare. Indeed, Wickmann, who studied the Swedish epidemic of 1905, divides the disease into eight clinical types, as follows: (1) Spinal poliomyelitic type. (2) Ascending or descending palsy. (3) Bulbar or

*Read at the annual meeting of the New Jersey State Pediatric Society, Atlantic City, June 27, 1910.

pontine type. (4) Cerebral type. (5) Ataxic type. (6) Polyneuritic type. (7) Meningeal type. (8) Abortive type.

In epidemics there are numbers of quickly fatal cases; also cases without palsy, or in which the palsy soon clears up. The writer has notes of cases

Fig. 2.—No. 7 of table; age 3 years; two months after attack; paralysis upper abdomen and both legs.

showing dysphagia, aphonia, ocular and facial palsies, and temporary palsy of the bladder and rectum. Unconsciousness and delirium are rare, except in the fatal cases, but apathy and moderate stiffness and retraction of the neck are not uncommon. It is well, however, to bear in mind that the spinal is the typical and common form, and that the other types are exceptional.

The limb palsies are of very irregular distribution and often escape observation until the prostration abates and the patient tries to get up. In other cases neuromuscular soreness and pains, which are very common, mark the palsy and often lead to a diagnosis of rheumatism. In a few cases there is no history of an attack, but lameness is noticed after the child begins to walk. In others, the child may wake up weak or lame in one leg, without constitutional symptoms. Better observation would doubtless reveal fever in many such cases. A few cases with moderate palsy never stop walking.

Abdominal palsy is quite common, though often overlooked. The New York Committee report only 8 cases from their material of about 750. The writer has notes of 16 cases where the abdominal muscles were paralyzed on one or both sides, indicated by a local or general protuberance of the abdomen, or a bulging caused by coughing or crying. In most of these cases there was arm palsy, and in all leg palsy at first. In nearly all, the arm palsy recovered; more or less permanent leg palsy remained, but was not always bilateral or severe. The abdominal palsy was sometimes in the upper part, sometimes in the lower, sometimes in the loin, on one or both sides; in two cases the entire abdomen was affected. The abdominal palsy was found in both fresh and older cases, and was sometimes an important factor in increasing the disability in sitting, standing, and walking. In half the cases there was marked or severe scoliosis.

In case 16 of the table walking was improved and backache relieved by trunk support alone.

The palsy, whatever its distribution, is always a palsy of relaxation and wasting, never spastic. The deep reflexes of the affected part are usually obliterated, but in a few cases of leg palsy the knee reflexes are exaggerated, as pointed out by Pierce Clark. Vasomotor paresis, shown by blueness and coldness, is nearly always present in the affected extremity. Wasting begins quickly, and, unless the muscles soon recover, is permanent in some degree. It usually involves the bones and other tissues, as well as the muscles. Growth is impaired, and a difference of one or two inches in the length of the limbs is common after a few years, when one extremity is paralyzed.

Fig. 3.—No. 10 of table; age 3; one week after attack; paralysis right side abdomen and chest; legs only slightly affected; scoliosis.

The active process is over in a few weeks, and there is nearly always a strong tendency to spontaneous improvement in some, at least of the paralyzed areas. Some muscles recover entirely, others partially, and others not at all. This is easily understood from the recession of the edema in the cord

and consequent relief of pressure on certain cells before they are destroyed. This improvement usually takes place in the first six months, but in the large majority of cases a considerable permanent atrophy and palsy in one or more limbs is left.

the ligaments, which yield in the end to the continual forcing. Permanent thigh flexion is usually combined with eversion and abduction; knee flexion, often with knock-knee and outward rotation of the leg; pes equinus often, with knee hypertension.

CASES OF POLIOMYELITIS WITH ABDOMINAL PALSY.

No.	Age	Sex	Age onset	Palsy at onset	Palsy permanent	Abdomen	Scoliosis	Present Condition
1 H.C.	18	m	16	Arms and legs	Left leg	Left upper and lower	Marked to left	Can walk a mile
2 E.E.	2	m	1½	Arms and legs	Left leg	Upper abdomen		Cannot walk
3 L.C.	9	f	4	Legs	R. leg ⅝ short	Right lower	Rt. dorsal, l. lumbar	Walks well

6 D.W.	2	m	13½	2 legs, l. hand	Both legs	Right side		Cannot walk
7 F.C.	3	f	3	2 legs, r. arm	Both legs	Upper, both sides		Cannot walk
8	21	f	19	L. arm, l. leg		Abdomen and back	Marked, to left	
9 G.S.	2	m				Abdomen, more on rt.	To left	
10 F.W.	3	f	3	Legs weak	Partial, legs	Rt. abdomen, rt. chest	To right	Attack 1 week ago
11 N.E.	4½	m	43¼	2 arms, r. leg	Right leg	Lower abd. and back		Walks
12 M.E.	15½	m	9½	Arms and legs	Right leg	Right abdomen		Cannot walk
13 L.H.	3	f	2½	Legs and neck	Double footdrop	Left side, severe		
14 I.L.	19¼	f	1	Arms, legs, neck	Right leg	Left side	To left	Cannot walk
15 J.D.	8	m	6	Arms and legs	Legs and hands	Right side		Cannot walk
16 M.W.	21	f	13	Legs	Both, partial	Abdomen nearly total	No scoliosis	Walks short distance, pain back

Another marked characteristic of the period of recovery is the tendency to the acquisition of fixed deformities, partly from accommodation to habitual postures, whether the result of voluntary choice, of unbalanced muscular action, or the pull of gravity, or of a combination of these factors. If the feet drop habitually, a fixed equinus may result in a few weeks; if the child is seated all day, fixed thigh and knee flexion often result.

Habitual strain also frequently results in deformity, or increases it, as when lateral deformity of the

Fig. 4.—No. 11 of table; age 4½; three months after attack; paralysis of abdomen and back.

foot, knock-knee, and hyperextension of the knee follow attempts to bear weight on the weakened and unsupported limb. The muscles which should guard the joint being disabled, the strain falls upon

The head of the humerus may fall away from the glenoid cavity from the continuous unsupported pull of gravity, and dislocation of the hip occasionally occurs from relaxation at that joint. In such cases

Fig. 5.—No. 12 of table; age 15 months; six months after attack; paralysis right abdomen and right leg.

the head of the femur can readily be slipped in and out of the socket, but cannot be retained in place without an operation to contract the capsule or to fix the joint.

Poliomyelitis is not known to be especially associated with other diseases, but often occurs accidentally with other affections, and some of the combinations may be puzzling. It is often seen in rachitic children, which, considering the frequency of rickets at the age most liable to poliomyelitis, is not strange. One should distinguish in these cases between essential palsy and hypotonia of rickets.

A girl had poliomyelitis at 4, at 10 she had an attack of chorea. The choreic movements were decidedly worse on the paralyzed side.

A baby was born with obstetric palsy of the right arm. At 8 months she had a typical attack of poliomyelitis with paralysis of both legs, the left recovering, and thereafter presented both forms of palsy.

A boy had an attack of poliomyelitis at one and a half, resulting in a cold, weak, and wasted left leg. He afterward developed tuberculosis of the lumbar spine. Without a careful history, this combination might be puzzling.

Cases of scoliosis are occasionally seen where the history or a careful examination of the limbs discloses a previous attack of poliomyelitis. Fixed scoliosis does not result in these cases from inequality of the length of the legs alone, but is due to paralysis of the spinal or abdominal muscles.

The diagnosis is practically impossible until the paralysis is declared, except in epidemics. In fever of sudden onset in summer, one should always test the muscular power of the limbs. Poliomyelitis has often been mistaken for cerebrospinal meningitis, typhoid fever, acute rheumatism, ptomain poisoning, and gastroenteritis. The flaccid motor palsy of sudden onset, without delirium or unconsciousness, distinguishes it from all of these. Landray's paralysis and many polyneuritides are undoubtedly in many cases nothing more than poliomyelitis.

Prevention lies in the avoidance of infected districts during an epidemic, isolation of the sick, and avoidance of over-exertion, over-eating, and sudden chilling in hot weather. A prophylactic serum may be discovered, but one would hesitate to give it to a healthy child, unless in an infected house; when the paralysis is declared, it is too late.

The prognosis as regards life is usually good, though in severe epidemics there is a moderate mortality. Partial recovery of power in some of the recently paralyzed muscles may be looked for; full recovery in all rarely takes place. After one year, usually after six months, further spontaneous recovery of power cannot be expected, and, if the child walks on a damaged limb without proper mechanical support, the deformity and weakness are often aggravated. Children can always be put on their feet and made to walk, even years after the attack, if one limb has fair power, no matter how weak its mate. Even if both legs are practically helpless, locomotion with crutches and splints may often be accomplished. Deformity of the limbs can nearly always be corrected, no matter of how long standing.

The conventional treatment by massage and electricity is completely ineffectual. Improvement occurs only during the stage of spontaneous recovery. This was publicly acknowledged by Dr. Bernard Sachs of New York, a distinguished neurologist, and Chairman of the Collective Investigation Committee of the New York Epidemic of 1907, at the Congress of American Physicians and Surgeons in May, 1910, in these words:

"I consider that time given to massage and electricity in these cases is time wasted; I cannot see that such methods do any definite good, and a great deal more benefit would be obtained by early institution of orthopedic measures."

This has been the practically unanimous opinion of orthopedic surgeons for a generation.

The most important indication in the first four to six weeks of the disease is rest in bed, in order to avoid irritating the site of the lesion and that the antitoxic forces of the body may have an opportunity to limit or repel the infection. As we do not yet understand the nature of the virus or how to combat it, the treatment should be hygienic and symptomatic; the bowels should be regulated and the child made comfortable, kept well nourished, and in the fresh air. Furthermore, as deformities, such as foot-drop, hip and knee flexion, and the like, may be acquired within a few weeks, these must be prevented by attention to posture, and, when necessary, by moderate stretchings and splinting. Even if the child is disposed to stand or walk, he should not be allowed to do so until a careful examination shows that the active process is over, and that the limbs and joints are strong enough to stand the strain. If not, he should be kept quiet until the proper supports are prepared. The prevention of strain and deformity, however, is not the only function of splints in these cases. There is nothing more damaging to a weak or palsied muscle than continuous elongation or stretching; on the other hand, if the paralyzed muscle is protected from traction and held in the shortened posture by proper splints, damage will be limited and a larger recovery of power, or at least a better utilization of latent but previously unavailable force, is often seen, and this may occur many years after the attack.

A man of thirty-seven, who had had poliomyelitis in early childhood, and had not placed his right foot on the ground for twenty-five years, came on a crutch with the leg dangling, the knee flexed to nearly a right angle, and the foot in extreme equinus. The leg was atrophied to skin and bone and there was no apparent power to extend the ankle. The knee was straightened and made stable by an excision, and the foot was brought up to a right angle after achillotomy. The result was very satisfactory, and, to the astonishment of everyone, good power of extension at the ankle was restored.

Many of these cases, more or less lame and helpless, seek the practitioner months or years after the attack. Though full recovery can no longer be expected, the condition of these advanced cases can nearly always be much improved. The indications are to improve local circulation, nutrition, static and muscular balance, and to correct deformity. It is extremely important that an accurate physical survey of the child should be made, the nature, degree, and cause of his disability defined, and measures devised for its mitigation. More of practical value can be learned from systematic testing of the voluntary power of the various muscle groups than from an electrical examination. Such tests are made by noting the patient's postures and movements, including locomotion, by asking him to execute the movements it is desired to test, and by noting the reaction to tickling the soles or to a light pin-prick. Weakened muscle groups, faulty muscle and static balance, inequality in length of the lower limbs, and vasomotor power should be observed.

For the nutritive and circulatory inadequacy and retardation of growth, vibration, local, spinal, and epiphyseal, is our most powerful remedy but one, namely, the normalized use of the part; that is, its use in proper relations and without undue strain.

The following history illustrates the treatment without splints or operation of a moderately early case of medium severity: A young man of eighteen came three months after his attack, limping badly, with a wasted right leg. He had two inches thigh atrophy, and three-quarters of an inch calf atrophy, partial quadriceps palsy, and pes equinovalgus. He could not completely straighten the knee nor invert the foot, and the heel cord was short. The patient was vibrated by a powerful vibrator at the sides of the spine and over the weakened muscles for a few minutes three times weekly. He was also given voluntary and resistive movements for weak muscle groups, the heel cord was stretched with Shaffer's stretcher, and he was trained in walking and in general posture. He had no mechanical support except Whitman plates for foot balance. After five months he walked several miles, and had no limp. His heel-cord contraction was gone, and the thigh had gained an inch and the calf three-quarters of an inch in circumference. The strong leg has also gained considerably from overuse, as is always the case.

The following case also illustrates treatment without splints or operation, and the stimulation of the growth of the limb in length through vibration:

A girl of two years and nine months came seven years ago with a weak and atrophied left leg and a pes valgus, as the result of an attack of poliomyelitis at seven months. As she walked fairly the shoe was raised and balanced, and a powerful vibrator was used over the knee epiphyses, spine, and leg, two or three times a week for several months each winter since. The child has improved markedly in general health and in walking, and in the strength and circulation of the leg. Each leg has grown ten inches in length in six years, the difference between the two being three-eighths of an inch, the same as at the beginning of treatment.

When there are fixed deformities, these must first be corrected, which, with the exception of scoliosis, may usually be done with simple tenotomies, myotomies, and fastiotomies, followed by proper retention apparatus, giving only needed support and imposing no unnecessary restriction. Abdomminal palsy and scoliosis may require trunk support through an orthopedic corset.

The matter of overcoming deformities and equalizing muscle balance is usually of far greater importance than the questions of full joint action or of general muscular development. When the opponents to a certain muscle are practically dead, to cultivate the functionating muscle only increases distortion and aggravates the difficulty. What is needed is not more power but a better balance and a better distribution of power, which may often be accomplished by orthopedic and surgical treatment, or by such a simple measure as balancing the shoe, or by increasing the thickness of the sole of the shoe on the short side.

When the only effect of the contraction of an active muscle is to distort the part and make useful function more difficult, it may be, and frequently is, the part of wisdom to lock up such a part by an operation or a brace—thereby vastly increasing symmetry and supporting power and sacrificing only deleterious action.

The points in the foregoing remarks to be emphasized are:

1. The not infrequent occurrence of poliomyelitis in adolescents and adults.
2. The fairly frequent occurrence of abdominal palsy.
3. The uselessness of massage and electricity.
4. The value of rest in bed in the early stage, and of orthopedic and surgical treatment, both early and late.
5. The necessity for a systematic statistical investigation by State Societies and Boards of Health.

BACTERIAL VACCINES IN THE TREATMENT OF DISEASES AMONG THE AGED.

By HENRY A. CRAIG, M.D.,

New Brighton, S. I., N. Y.

Assistant Physician and Bacteriologist, Sailors' Snug Harbor Hospital.

The successful use of bacterial vaccines in the treatment of disease necessitates an ability on the part of the patient to react to them. Active immunity to the infecting agent is produced by an increase of the opsonins, and probably other cooperative factors, very different from the immunity produced by the injection of diphtheria antitoxin, for instance, in which case the patient is a mere passive agent. In the latter case, the immunizing agent is actually introduced into the system, already prepared; in the former, certain body cells are stimulated to produce the immunizing agents, and in case they have too little vitality to do so the treatment fails.

The foregoing should not lead to a belief that bacterial vaccines have no value among patients debilitated by age and chronic disease. In this hospital 77 per cent. of the patients have been found to be between sixty and eighty years of age,* and the principal clinical diagnoses among nearly two thousand admissions to the hospital during the past three and one-half years are as follows, expressed in percentages:

Acute alcoholism	27.	Hemiplegia	2.4
Gastritis	9.	Asthma	2.3
Chronic endocarditis	5.4	Myocarditis	1.5
Rheumatism	4.5	Malaria	1.5
Debility	4.	Diabetes	1.
Bronchitis	3.8	Insane	1.
Chronic nephritis	3.7	Pulmonary Tuberculosis	.9
Cancer	3.5	Blind	.9
Senility	3.3	Fracture of femur	.8
Influenza	3.	Locomotor ataxia	.8
Pneumonia	2.4	Gout	.7

The average mortality among the above cases was 13 per cent., and the principal causes of death were:

Chronic nephritis	18.5	Pulmonary tuberculosis	3.7
Cancer	13.	Enterocolitis	3.
Chronic endocarditis	12.	Senile gangrene	2.
Senility	8.	Locomotor ataxia	1.2
Pneumonia	6.5	Diabetes	1.2
Pyleonephritis	5.	Angina pectoris	.8
Cerebral hemorrhage	4.5	Aneurysm of aorta	.8
Senile dementia	4.	Fracture of femur	.8

Of the cases coming to autopsy, the principal causes of death are shown in the following table:

*Below 60 years of age, 11 per cent.; between 60 and 70, 35.5 per cent.; between 70 and 80, 42 per cent.; between 80 and 90, 11 per cent.; over 90, 0.2 per cent.

Cancer	39.	Peritonitis	2.7
Chronic nephritis	16.	Purulent pericarditis	2.7
Pyelonephritis	15.	Subdiaphragmatic abscess	1.
Chronic endocarditis	9.5	Empyema	1.
Pneumonia	5.	Abscess of liver	1.
Aneurysm of aorta	2.7	Perinephritic abscess	1.

Thirteen per cent. of all the deaths were due to cancer, with the following distribution:

Stomach	19	Colon	3
Stomach and liver	16	Cecum	3
Liver	9	Prostate	3
Sigmoid and rectum	9	Face	3
Pancreas	6	Liver and Pancreas	3
Bladder	6	Larynx	3
Sigmoid and liver	6	Esophagus	3
Mouth and tongue	6		

Thirty-five per cent. of all the fatal cases of cancer were primary in the stomach; 34 per cent. were in the liver, the greater number of these being secondary to malignant disease of some part of the gastrointestinal tract; 22 per cent. were in some part of the large intestines. Of the new admissions to the Harbor (not necessarily hospital patients) 26 per cent. have chronic nephritis, 17 per cent. have chronic endocarditis, and a much larger proportion are suffering from myocardial degenerations. Three per cent. have sugar in their urine, although but 1 per cent. of the patients die directly from diabetes.

Bacterial vaccines, prepared in our laboratory, have been employed among the classes of patients above enumerated and, in almost all instances, under physical conditions which have long been considered adverse to favorable prognoses.

Case I.—Mr. M., age 72. *Osteomyelitis of the tibia, septicemia, acute endocarditis, cerebral embolism.* The prognosis was bad from the start, on account of the age and general condition of the patient. He had severe chronic nephritis and arteriosclerosis. Heart considerably hypertrophied but no murmurs present. The process began suddenly with a chill, four days before the local condition presented itself, with a temperature of 102.6, leucocytes 20,700, polynuclears 74 per cent. The inflammation of the superficial tissues extended as high as the knee, with especially great swelling and edema about the left ankle. Temperature 102-104, leucocytes 20,700, polynuclears 79 per cent. Three incisions with local analgesia were made over the lower end of the tibia down to the bone. About 100 c.c. of pus found and bare bone felt. Cultures from the pus showed *Staphylococcus pyogenes albus.* The treatment consisted of wet bichloride dressings, through-and-through irrigations b.i.d., and Bier's hyperemia method. Ten days later the local condition had greatly improved, drainage was free, and the inflammation confined to the lower end of the leg and about the ankle; but the general condition of the patient was failing. Temperature varied between 100° and 102.5°. Several days later gangrene set in about the ankle posteriorly; patient developed a soft, blowing mitral systolic murmur and a left facial paralysis. Apparently an acute endocarditis and cerebral embolism had developed. Blood cultures revealed the *Staphylococcus pyogenes albus.* Patient was given an injection of autogenous staphylococcus vaccine, repeated in forty-eight hours. Despite the hopeless condition that the patient was in he reacted fairly well to the vaccine, the temperature dropping from 106 to normal for the only time during the course of the disease. He died very suddenly during an attack of vomiting, probably due to a second cerebral embolism. No autopsy.

Case II.—Mr. C., age 76. *Lupus vulgaris.* Patient had been afflicted with lupus for years, with deep ulcers all over the face and about the eyes. Had been treated with antiseptic lotions and ointments, curetting the sloughs, *x*-ray, almost to the point of burning, etc., with but little benefit. As the result of the ulceration and the new connective tissue his face was terribly scarred. It was covered with crusts, with supupration going on underneath, and with many ulcers. In fact, his appearance was so repulsive that some of his fellow-patients objected to his being at table with them. His eyelids were so scarred and deformed that he could not open them, except slightly on one side, where a plastic operation had been performed, making use of the occipitofrontalis muscle. The principal organism found was the *Staphylococcus pyogenes aureus.* The patient was given an autogenous vaccine, 1,000,000,000 at a dose, every five to nine days, for about three months, at the end of which time all the ulcers on the face had healed except a deep one on the point of the chin, which had hard, indurated, everted edges, and looked malignant. Subsequently a small piece taken from its edge showed it to be an epithelioma. About this time the patient began to complain of great pain in the abdomen and diarrhea, and had to be given morphine. A mass could be felt indistinctly in the left inguinal region, and the liver was greatly enlarged. The patient failed steadily for the next three months, and died after being comatose for three days. Autopsy revealed a carcinoma of the sigmoid and an enormous secondary growth in the liver. No ulcers on the face at the time of death, except the epithelioma on the chin.

Case III.—Mr. A. *Osteomyelitis of the femur.* Following a previous injury the patient had a deformity of the left leg, and insisted that an attempt be made to straighten it. In an attempt to overcome this deformity osteoclasia of the left tibia and fibula was performed at the junction of the upper and middle thirds of the leg. Gangrene set in almost immediately as a result of a large hematoma—the entire calf and soft tissues about the wound sloughed away. The foot and lower part of the leg (which still partly retained their vitality and were cold and cyanotic, but not gangrenous) were separated from the upper part of the leg by an interval of about four inches, and connected merely by the large nerves and blood vessels surrounded by a little tissue. The dead ends of the bones protruded into the wound a couple of inches. Patient was running a septic temperature, but amputation was postponed trying first to get him into a better general condition. The knee joint became infected six weeks after the original operation, and with the patient in a desperate condition amputation was performed at the junction of the middle and lower thirds of the thigh. No attempt was made to form flaps, and the wound was left wide open. Patient left the operating table barely alive. Ten weeks later the patient was in fairly good condition, except that he was suffering from the effects of a toxic peripheral neuritis of the right arm, and was operated upon again; at this operation four inches of the femur had to be sacrificed to allow formation of the flaps. Patient stood the operation well, but the stump would not heal. Suppurating sinuses remained at each angle of the wound and in the center of the stump, all communicating. He remained in this condition for the next nine months, in spite of every effort being made to get the sinuses to heal. At the end of this time he

was operated upon again, and a sequestrum about the size of a half dollar, which had partly separated from the end of the bone, was removed. Still the wound would not close; a couple of communicating sinuses were left at the angles of the wound, discharging about two c.c. of pus daily. Cultures from the same showed the *Staphylococcus pyogenes albus*. He was treated for the next month by an injection every three to five days of an autogenous staphylococcus vaccine in doses of 250,000,000 to 1,000,000,000. One sinus soon closed, another small sequestrum was removed, and the stump healed at last. He has had no further trouble with it (eight months later), and now wears an artificial leg with great satisfaction.

Case IV.—Mr. W., age 72. *Cellulitis of right foot, leg, and thigh.* Prognosis was bad on account of the age of the patient, the severity of the infection, and the presence of chronic endocarditis. The infection followed the paring of a corn and spread rapidly up through foot and leg, in spite of amputation, first of the toe, then leg, and finally of midthigh, the wound being left open widely for drainage. Cultures from the tissues showed streptococcus and staphylococcus. The microscopic examination of the pus revealed, in addition, the *Bacillus aerogenes capsulatus*. The tissues were infiltrated with gas; practically no pus present. The infection was controlled at last by autogenous vaccines of streptococcus and staphylococcus, injections of permanganate of potassium into the tissues, in and above the site of the infection, free drainage, wet dressings, etc. After the infection was controlled and the stump granulating, a final operation was performed to make satisfactory flaps for the stump. Patient has regained his usual health, wears an artificial leg, and appears in exceptionally fine physical condition.

Case V.—Mr. M., age 73. *Streptococcus cellulitis of hand, chronic nephritis, and very severe arteriosclerosis.* The infection resulted from striking a man in the mouth, a tooth causing an abrasion on the right index finger near the distal end of the proximal phalanx. A periostitis of the phalanx followed, which was incised and drained, but the infection spread, necessitating the amputation of the finger. However, the infection spread to the hand, resulting in a diffuse cellulitis of the entire hand, extending above the wrist. Cultures from the pus showed almost a pure culture of streptococcus. Toxemia severe. Rather than mutilate or amputate the patient's only remaining hand (inasmuch as he had lost his left arm at the elbow years ago), the attempt was made to control the infection with a vaccine. The hand was treated with wet dressings and an autogenous streptococcus vaccine every two or three days, for four doses, thirty-five to fifty million at a dose, which controlled the infection very satisfactorily. The wound granulated and the patient made a very satisfactory recovery. Except for the loss of the index finger, but little permanent disability exists.

Case VI.—Mr. F., age 67. *Acute appendicitis.* Patient had chronic nephritis and was very alcoholic. The attack came on at the end of a prolonged spree and the patient was on the verge of delirium tremens. Condition was very bad for an operation. He was brought to the hospital, with all the classical symptoms and signs of a severe, acute attack of appendicitis. Vomiting almost continuously. Great pain in the abdomen, tympanites, and rigidity. Extreme tenderness over the region of the appendix. Temperature 101.6, pulse 110, leucocytes 22,000, polynuclears 88 per cent. Bowels cleaned by enemata. Absolute rest in bed. Nothing by mouth except very small quantities of water. Pain controlled by anodynes, ice-bag, etc. The next day all the symptoms were much worse. Temperature 102°, pulse 120, leucocytes 26,680, polynuclears 94 per cent. Great pain in the abdomen, very marked tenderness and rigidity. Still vomiting. He was given 150,000,000 of a vaccine, made from the interior of an appendix removed the day before (from a patient suffering from an acute appendicitis) and consisting of a mixture of streptococci and colon bacilli. The temperature fell by lysis during the next two days to normal. The pain, tenderness, and rigidity of the abdomen gradually improved for the next four days. Out of bed one week after entrance into the hospital, and discharged from the hospital four days later, entirely recovered.

Case VII.—Mr. C., age 66. *Demented. Streptococcus cellulitis of the right leg and thigh.* The infection started from an abrasion on the outer side of the right leg, just above the ankle. A local abscess resulted, which was incised and drained. This did not control the infection, however, which spread up the leg and thigh to the body. The tissues about the incision and of the thigh as high as the body were red, swollen, indurated, and tender. Not very much discharge from the wound. Temperature high, pulse rapid. Examination of the discharge showed a pure culture of the streptococcus. Patient was given an autogenous streptococcus vaccine every four days in doses of fifty, seventy-five and one hundred million. The infection gradually subsided, and in three weeks had entirely disappeared, except for a small sinus, about half an inch deep, leading upward from the original incision into the superficial tissues, and patient was able to be up about the ward in a wheel chair. However, he gradually failed and died one month later of general debility and dementia.

Case VIII.—Mr. M., age 82. *Ischiorectal abscess.* Six months before the patient had developed a very large ischiorectal abscess which was operated upon and a large quantity of pus and sloughs removed. The incision closed imperfectly, leaving a discharging sinus which would close for a few days and then open and discharge again for some time. Patient's general condition was too bad to attempt any very radical measures. He was treated by an autogenous colon vaccine, made from the discharge, in doses of fifty, one hundred and one hundred and fifty million every three days. The beneficial effect was very marked. The original incision closed and the perineum looked better than it had for months. At the present writing, nearly a month later, the condition is very satisfactory, the troublesome sinus being entirely closed.

Bronchitis. These were all severe cases of acute bronchitis, with temperatures between 100° and 105°, many râles over both lungs, and in the two latter cases, at least, there was suspicion of the presence of bronchopneumonia, but on account of the complicating emphysema small areas of consolidation could not be detected. The cases were all as severe as ordinary cases of pneumonia. All the patients were old and feeble, and had chronic nephritis, and the prognosis seemed unfavorable in each case.

Case IX.—Mr. C., age 86. *Arteriosclerosis very marked; heart greatly hypertrophied and its action irregular and intermittent.* Came to the hospital

with a severe attack of acute bronchitis, following exposure two days before. Had a severe, hard, dry cough every few minutes, with very little expectoration. Great soreness beneath the sternum. Scattered râles over the posterior of both lungs. No evidences of consolidation. Temperature 101°.

A single dose of vaccine, 50,000,000, brought the temperature to normal, and the patient rapidly recovered from the acute symptoms but was so feeble as the result of his attack that he was not expected to live for some time, and did not recuperate sufficiently to leave the hospital till seven months later. He is enjoying vigorous health for one of his years at the present writing.

Case X.—Mr. A., age 74. Came into the hospital with an attack of acute bronchitis due to exposure. Examination of the lungs revealed emphysema and coarse râles over the posterior of both lungs. Lucocytes 13,000, polynuclears 84 per cent. Was treated for a week by the usual measures with no improvement. Temperature between 100° and 102°, leucocytes 15,400, polynuclears 93 per cent. Large quantities of mucopurulent sputum. The temperature then suddenly went up to 105°, with neither chill nor particular change in the physical signs in the lungs. A single dose of autogenous vaccine, 200,000,000, was given; the temperature fell by lysis and all the symptoms and signs rapidly cleared up and the patient made an uneventful recovery. He is still too feeble, mentally and physically, to leave the hospital, at the present writing, one month later.

Case XI.—Mr. S., age 84. Came into the hospital complaining of having taken a severe cold, of feeling chilly, and of general pains. Coughing almost continuously; not much expectoration. Temperature at entrance 104.4°, pulse 100, weak and irregular; respirations 30. Face flushed and cyanotic. Examination of the lungs revealed fine and coarse râles over both bases, especially marked at the left base; but too much emphysema was present to detect any small areas of consolidation, if present. Leucocytes 12,000, polynuclears 80 per cent. He was treated for several days by the usual methods with little or no improvement. Temperature between 100° and 102°. Was then given an injection of autogenous vaccine, 35,000,000, mostly streptococci. This was repeated in forty-eight hours by a dose of 50,000,000. The temperature fell by lysis and all the symptoms and signs rapidly cleared up. He was discharged from the hospital five days later and is in excellent health.

Case XII.—Mr. C., age 86. *Very severe acute bronchitis and asthma.* Was brought to the hospital suffering intensely from dyspnea; incessant cough, with very profuse frothy expectoration; pain in the chest, and marked cyanosis coming on a few hours before, though he had been feeling badly for several days. Temperature 103.4°, pulse 120, respirations 30. Lungs emphysematous. Coarse râles present in every part of both lungs. After four days of treatment by the usual methods the bronchial condition was but little changed, except that the asthma had improved somewhat. Temperature running between 100° and 103°. On account of the asthma and emphysema it was impossible to detect the presence or absence of any small areas of consolidation. He was given 200,000,000 of an autogenous vaccine, repeated in twenty-four hours by 300,000,000. The temperature fell by lysis and three days later was normal. Convalescence was slow, but satisfactory. Was discharged from the hospital three weeks after entrance. No attempt was made in these bronchitis cases to isolate any one particular form of bacteria for the vaccine. The vaccines contained all the forms that grew from the washed sputum and the dosage was varied according to the predominating form of bacteria.

Pneumonia. The use of the pneumococcus vaccine has been very successful here in the treatment of lobar pneumonia, especially when the age of the patients, their complicating chronic diseases, and personal histories are considered. The mortality among similar pneumonia patients here, previous to the use of the vaccine was 66 per cent. A series of six cases of lobar pneumonia among the aged, treated by vaccines, has been published in detail, together with the method of preparation and administration.* Although these cases were all typical and severe cases of lobar pneumonia, two of them being double, and the patients between 66 and 83 years of age, they all recovered, indicating very markedly the value of the vaccine treatment.

Case XIII.—Mr. M. Had chronic nephritis and marked hypertrophy of the heart. He was very alcoholic and the present attack came on at the end of an alcoholic debauch. He was brought to the hosptial in a condition bordering upon collapse. Pulse rapid (112), irregular and intermittent. Extremities cold and cyanotic. Retching and vomiting almost continuously. Had had a chill several hours before entrance. Complained of great pain in the abdomen. Temperature 103°, leucocytes 17,600, polynuclears 96 per cent. No physical signs in the lungs. The pneumonia did not reveal itself till thirty-six hours later, when he began to have a short, hacking cough, pain in the right side, and rusty, tenacious sputum containing great numbers of pneumococci. The next day the patient had developed a frank pneumonia of a large part of the right lung, complicated with an extensive pleurisy which caused great pain in the right side. Still vomiting. Coughing almost continuously and expectorating considerable bloody sputum. Temperature 102°, pulse 120, irregular, intermittent, and of low tension, respirations 32. The prognosis was considered hopeless, and last rites of his church administered. He was given pneumococcic vaccine, 35,000,000. The next day his general condition was somewhat better, but the lower and middle lobe of the right lung were solid. He was given a second dose of autogenous vaccine, 50,000,000, forty-eight hours after the first. Four days later the temperature was normal and the lung softening. Out of bed two days later, with only a little pain in the right side, due to the pleurisy. Was discharged from the hospital ten days later, in excellent condition.

Case XIV.—Mr. L., age 90. Came to the hospital complaining of pain in the left side and severe cough. Said that he had caught a severe cold the day before. Was chilly, but had had no definite chill. Patient was senile and feeble. Arteriosclerosis very marked. Temperature 101°, pulse 126, respirations 28, leucocytes 18,000, polynuclears 82 per cent. Had a severe, hard cough; slightly rusty sputum, containing pneumococci. Slight dullness and many fine crepitant râles over the posterior of the left lower lobe. He was given pneumococcus vaccine, 35,000,000. Three days later the temperature was normal, and the patient sitting up. Cough was much less and the physical signs had nearly disappeared from the lung. He was discharged from the

*Medical Record, February 12, 1910.

hospital nine days after entrance, having entirely recovered his usual state of health, which is remarkably good for one of his years.

Case XVI.—Mr. M., age 72. *Had chronic nephritis, spondylitis deformans, and was very feeble.* The patient was brought to the hospital, complaining of a short, dry, hacking cough and distress in the right side. Said that he had had a chill the day before and had been feeling badly for several days. Temperature 101°, pulse 80, respirations 26. Examination of the lungs revealed a few fine crepitant râles over the posterior of the lower lobe of the right lung. No sputum. The next day he had typical rusty sputum containing large numbers of pneumococci; a severe pain in the right side and a temperature of 104.6°. Dullness and many fine crepitant râles over the posterior of the lower lobe of the right lung. He was given pneumococcus vaccine, 50,000,000. The temperature fell by lysis and was normal three days later. He was up and about the ward one week after entrance into the hospital and his lungs were in normal condition. He did not regain his strength, however, and died a month later of general debility.

Case XVII.—Mr. W., age 67. *Had chronic nephritis and chronic endocarditis.* Patient was brought to the hospital complaining of a severe cough, shortness of breath, pain in the left side and fever. Said that he had had a chill two days before. He was feeble, cyanotic, and suffering from dyspnea. There was consolidation of the lower lobe of the left lung, which, the next day, seemed so very flat on percussion as to arouse the suspicion of the presence of fluid. Was aspirated, but no fluid found except a little frothy blood. Temperature continued between 101° and 103°. Leucocytes 25,000, polynuclears 90 per cent. He was treated by the usual methods, stimulation, etc., plus the injection of vaccine once a day for three days in doses of twenty-five to fifty million. Six days after entrance the temperature was normal and the lung resolving, but the patient did not improve in his general condition and five days later he suddenly died of cardiac failure. Autopsy showed the left lung in the last stages of resolution and with no remaining consolidation. Very extensive fibrinous pleurisy on the left side. Pericardium contained about eight ounces of thick creamy pus. The patient had died of purulent pericarditis.

Case XVIII.—Mr. B., age 80. Patient was brought to the hospital in a very feeble condition with considerable cough, pain in the right side, and scanty, rusty sputum containing pneumococci. Temperature 101°, pulse 100, respirations 26, leucocytes 14,000, polynuclears 80 per cent. Dullness and many fine crepitant râles over the posterior of the lower lobe of the right lung. He was given pneumococcus vaccine 50,000,000. Three days later the temperature was normal and the lung clearing. Out of bed three days later, but is so senile and feeble that he is still unable to leave the hospital, at this writing, two months later.

Case XIX.—Mr. L., age 69. *Had severe chronic nephritis.* Patient was brought to the hospital complaining of severe pain in the right side; hard, dry cough with bloody expectoration and chilly sensations. He was very anemic. Arteriosclerosis very marked. Heart hypertrophied. Temperature 102°, pulse 90, respirations 26. Later in the day temperature rose to 106°, pulse 110, respirations 32, leucocytes 22,000, polynuclears 87 per cent. There was beginning consolidation of the posterior of the right lung with typical rusty sputum containing large numbers of pneumococci. He was given pneumococcus vaccine 50,000,000. Two days later the pneumonia had spread to the lower lobe of the left lung. Temperature 104.2°, pulse 96, respirations 44. The respiration was very much embarrassed on account of the amount of the lung involved. The same dose of the vaccine was repeated. The next day the patient was in a very bad condition. The entire left lung was solid as well as the lower lobe of the right; 75,000,000 of the vaccine administered. The next day the temperature began to fall and the right lung to soften, but the heart was beginning to fail. Pulse very rapid, weak, and irregular and did not respond to stimulation. Died the next day of cardiac failure. Autopsy showed the right lung almost entirely resolved; the lower lobe of the left lung nearly resolved and the upper lobe of the left lung in the stage of gray hepatization. The heart was greatly dilated and filled with blood clots. Heart muscle very friable. Kidneys showed chronic interstitial nephritis. In this last case there was little or no response to the use of the vaccine. But in all the other cases the reaction seemed marked and apparently demonstrated the value of the treatment. The mortality of this series of pneumonia cases is 16 per cent., a marked contrast to the 66 per cent. mortality in similar cases, treated here, prior to the use of the vaccines.

COMPLEMENT-FIXATION TESTS IN THROMBOANGIITIS OBLITERANS.

By LEO BUERGER, M.D.,

AND

DAVID J. KALISKI, M.D.,

NEW YORK.

CLINICAL SECTION BY DR. BUERGER.

The etiology of the disease to which I have applied the term "thromboangiitis obliterans"[1] (which has been variously called "endarteritis obliterans" and "Angiosklerotische Gangraen" by German authors), is still a matter for investigation. Some authors have attributed the lesions to lues, because temporary improvement in the subjective state as well as amelioration of some of the clinical manifestations, may occur after the administration of mercury. I have elsewhere[2] alluded to the fact that a cure by antiluetic treatment, or in fact by any other known drug, is hardly to be expected, for the symptoms are dependent on the disturbance of circulation produced by extensive obliteration, first by occlusive coagulation of blood and later by organization of connective tissue. Neither the recent thrombi nor the vascularized, canalized, obturating tissue can be removed by medication.

Before advancing arguments for and against the possible syphilitic origin of this remarkable disease, let me give a brief description of the usual clinical manifestations.

The malady is still frequently confounded with erythromelalgia, Raynaud's disease, and arteriosclerosis of the vessels of the lower extremities. Beginning in most instances with indefinite pains in the sole of one foot, in the ankle, or in the toes, the patients soon notice that they are disturbed in their walk by the sudden onset of cramp-like sensations in the calf or elsewhere in the leg. These feelings make them take frequent rests, often inducing them to investigate the condition of their

limbs. Some take off their shoes and rub the parts in the hope of either dispelling the pain or banishing the uncomfortable numbness in the toes and feet. Others say that the feet become cold and numb when the temperature is low and when the weather is inclement.

After the lapse of weeks, months, and even years, evidences of trophic disturbance make their appearance. Following the cutting of a nail, or without apparent cause, an abraded spot or hemorrhagic bleb, a pustule, or a dry, dead patch of skin develops near the tip of one of the toes or under a nail. Now the local pain becomes excruciating during the night as well as day, so that some of the sufferers beg for amputation of the affected part.

It is during the first attack of trophic disorder that the physician usually notices another characteristic symptom, namely, a peculiar blush of the toes and forepart of the foot, sometimes extending to the ankle or slightly above, when the limb is in a dependent position. Upon allowing the limb to hang down, the affected toe soon assumes a bright red hue which is seen to pass to the other toes and then up the back of the foot for a variable distance. The elevated extremity, on the contrary, rapidly becomes blanched. Sometimes the superficial ulcer will heal under conservative treatment and the patient will either recover perfectly or his symptoms will become chronic. At this period his limb will show scars left by previous ulcers; the dorsalis pedis and the posterior tibial artery usually fail to pulsate, and ischemia in the elevated position and redness or "erythromelia" in the dependent position are regularly elicited. Sooner or later, however, an ulcer will give way to dry gangrene, and amputation will be the issue.

Because of the striking condition of redness in the dependent position, and because of the increase of local pain when the limb is hanging down, a number of clinicians have been wont to diagnosticate "erythromelalgia" in these patients. Some cases have been regarded as examples of Raynaud's disease, because in them the symptoms of blanching and cyanosis of the parts were prominent features. Athough resembling erythromelalgia and Raynaud's disease in a number of symptoms, the picture of thromboangiitis obliterans, as we see it, is so characteristic and definite that we must regard it as a distinct clinical entity.

Pathological studies* have shown the following: Most of the larger arteries, and sometimes the veins as well, are obliterated over a large extent of their course. All stages in the occlusive change may occur in the various vessels of an extremity or in the same vessel in different parts of its course. The closure of the vessels is effected by red obturating thrombi; these become organized, vascularized, and canalized. Recent red thrombosis may involve large portions of arteries or veins and is not secondary to the gangrenous process. It occurs even when no gangrene is present. In short, we are dealing with lesions of considerable extent apparently initiated by the formation of occlusive thrombi, chiefly in arteries, but not confined to these, followed by organization or healing with an attempt at the production of a collateral circulation.

From the pathological standpoint the marked periarteritis, which is so frequently a characteristic lesion, might suggest syphilis. However, a thorough study* made by Miss A. Oppenheimer and the author, failed to reveal the presence of the *Spirochæta pallida* in a large number of vessels removed from amputated limbs. In short, nothing definite was ascertained in our histological studies to throw light on the etiology of the process.

Clinically, I have rarely been able to elicit a history of lues. Only two patients out of a total of about 80 cases had had a syphilitic infection. It is rather striking that males only seem to be affected by the disease. Were syphilis responsible, we should expect a certain proportion of female patients in our large list.

In view of the fact that the suspicion of lues is still so frequently entertained in attempts at explaining the cause of the condition, it seemed advisable to make the usual serological tests. Twenty-nine consecutive cases, as they came under my observation at Mount Sinai Hospital, in the dispensary, and in my private practice, were tested by Dr. Kaliski. The clinical course of many of these patients had been followed by me for a number of years, and careful notes made. In 17 cases, the diagnosis was confirmed by the pathological examination of vessels of the amputated limbs; in the remaining twelve the diagnosis was clear, and not a single doubtful case was included in the list.

For the sake of completeness, brief abstracts of the twenty-nine cases are here given.

Case I.—M. P., 34 years old; Russian Hebrew; admitted to Mt. Sinai Hospital, May, 1908. Denies luetic infection. A history of migrating phlebitis of the left forearm and arm, and of the left saphenous vein. Physical examination: Absence of pulsation in dorsalis pedis and posterior tibial arteries; marked erythromelia of the right leg. Same physical signs in the left leg with evidences of thrombophlebitis of the long saphenous vein. Dec., 1908, trophic ulcers appeared and walking was impossible.

Case II.—A. G., 40 years old; Austrian Hebrew; seen Feb. 12, 1909. No history of syphilis; father of three healthy children; pain along inner side of left leg and ankle for a year, especially on exertion. Physical examination: Absence of pulsation in right femoral, popliteal, posterior tibial, and dorsalis pedis arteries. All arteries of the left leg pulsate. Dec., 1909, migrating phlebitis of the right external saphenous. Jan. 30, 1910, typical erythromelia, marked ischemia on elevation, and a hard nodule in the course of the external saphenous vein.

Case III.—D. B., 35 years old; Russian Hebrew; admitted to Mt. Sinai Hospital, July, 1904. No evidence of lues. Attacks of phlebitis involving arm and leg veins. In 1905, symptoms of thromboangiitis obliterans. During 1907 a small gangrenous area appeared at the tip of the middle finger of the right hand. During 1908 and 1909 the severe type of the disease without gangrene developed in both legs. Trophic ulcers, marked erythromelia and pulseless vessels below the groin.

Case IV.—H. R., 32 years old; Russian Hebrew; Mt. Sinai Dispensary, 1908. No history of lues. The right leg was the seat of migrating phlebitis; all the vessels pulsating. The left posterior tibial and dorsalis pedis arteries could not be felt. In Dec., 1908, ischemia and erythromelia of both legs were marked. Jan. 31, 1909, amputation of the left leg at the upper fourth for beginning gangrene of the big toe. Pathological examination showed occlusion of the dorsalis pedis, peroneal, plantar, and posterior tibial arteries.

Case V.—S. R., 38 years old; Austrian Hebrew; Mt. Sinai Hospital, May 15, 1909. No history of

*Complete histological studies will be reported in the near future.

lues. No children. In 1903, ulceration of the big toe of the left foot. One-half year later amputation of the toe for gangrene. Ten weeks ago severe pain in the third toe of the right foot. This has now become gangrenous. Physical examination showed the usual typical phenomena. May 17, 1909, amputation of the third toe; June 16, amputation of the second and fourth toes, and finally, July 23, a Gritti amputation was necessary. Pathological examination of the vessels showed the typical lesions of thromboangiitis obliterans.

Case VI.—K. B., 30 years old; Russian Hebrew; Mt. Siani Hospital, Dec. 15, 1909. No history of lues. Onset three months ago with pain in the sole of the left foot; some difficulty in walking for about six months. Symptoms of intermittent claudication have developed lately, and after a slight trauma two months ago the big toe of the left foot became ulcerated. Since then the fourth toe has also become ulcerated and is gangrenous at the tip. Physical examination: Ulceration of the big toe, superficial gangrene of the fourth toe, a small granulating wound at the base of the fifth toe, and marked erythromelia. Absence of pulsation of the left dorsalis pedis, posterior tibial and popliteal arteries. The vessels of the right leg pulsate normally.

Case VII.—M. Y., 44 years old; Christian Pole. No history of lues. Has no children. Five years ago a history of trouble in the right leg, ulcer formation, and migrating phlebitis. For two years pain in the ankle and calf of the left leg. For two months pain in the second toe of the left foot and a feeling of coldness. Physical examination: Marked blanching on elevation, and erythromelia. The second toe is becoming gangrenous at the tip.

Case VIII.—R. L., 60 years old; Russian Hebrew; Mt. Sinai Hospital, Aug. 31, 1908. No history of lues. Four years ago had the same trouble in the left leg which was amputated at that time. For two years has had a sensation of coldness in the right foot; pain on walking. Four weeks ago the pain became so severe that walking was impossible and the forepart of the foot began to turn red. A gangrenous patch of skin developed at the outer border of the big toe. Physical examination: Absence of pulsation in the dorsalis pedis, posterior tibial, popliteal, and femoral arteries on the right side. Erythromelia even in the horizontal position. Sept. 2, amputation at the lower third of the leg. Pathological examination showed the typical lesions of thromboangiitis obliterans.

Case IX.—E. B., 36 years old; Russian Hebrew; Jan. 17, 1909. No history of lues. Onset with thrombophlebitis in the region of the inner aspect of the right leg, preceded by cramp-like pains on walking for more than a month. Physical examination: Phlebitis of the saphenous, absence of pulsation in the dorsalis pedis and posterior tibial arteries of both legs; cyanosis of the big toe of the right foot. March, 1909, the discoloration of the big toe persists and there are no trophic disorders. Symptoms of intermittent claudication still present.

Case X.—M. K., 44 years old; Russian Hebrew; Mt. Sinai Hospital, Dec. 8, 1908. No history of lues. Presents the typical association of migrating phlebitis. Onset with phlebitis, later, cramps in the calf of the right leg after walking a short distance. Physical examination showed evidences of circulatory disturbances in the right lower extremity; pulseless dorsalis pedis and posterior tibial arteries; typical erythromelia and ischemia. In Feb., 1909, gangrene of the fourth toe; Feb. 23, Gritti amputation. Pathological examination showed typical lesions of thromboangiitis with occlusion of the plantars, peroneal, posterior tibial, and lower part of popliteal arteries.

Case XI.—J. C., 45 years old; Russian Hebrew; Mt. Sinai Hospital May, 1908. No history of lues. Onset four years ago with symptoms in the right leg; pain in the sole of the foot lasting for eight months, followed by complete cure, the only evidences of previous disturbances being the absence of pulsation of the dorsalis and posterior tibial arteries. Symptoms in the left foot for about a year leading to gangrene of the big toe. Physical examination: Typical erythromelia and ischemia and gangrene of the big toe spreading to the dorsum. Amputation at the knee. Pathological examination showed typical lesions of thromboangiitis obliterans.

Case XII.—B. B., 34 years old; Russian Hebrew; June 17, 1909. No history of lues. Had pain in the right calf on walking eight years ago, together with hard cords and lumps over both forearms and legs. Since then recurring attacks of phlebitis in the territory of the saphenous. For two years the left leg has given him concern. In Jan., 1909, ulcers developed at the tip of the big toe of the left leg and also over the little toe of the right. Physical examination: Toes of the right leg have a tense, reddened appearance. There are the usual evidences of trophic disorder; marked erythromelia; ischemia in elevated position is intense and excites severe pain. The femoral artery pulsates; the popliteal, posterior tibial, and dorsalis pedis cannot be felt. The left leg is similarly affected. There is a trophic ulcer at the tip of the big toe and all the vessels, femoral included, fail to pulsate.

Case XIII.—A. G., Russian Hebrew, 33 years old; Nov. 27, 1908. No history of lues. Three years ago, pain in the sole of the left foot on walking which has been so severe for the past year that he is now unable to walk. In Oct., 1907, an ulcer developed on the fourth toe which healed after several weeks. Complains of coldness and pallor of the feet when the weather is inclement. Physical examination: Absence of pulsation of the right dorsalis pedis and of the posterior tibial and dorsalis pedis of the left foot. Both feet are cold and slightly ischemic in the elevated position. Patient has been kept under observation until April, 1910. Symptoms of intermittent claudication persist, but no trophic ulcers have developed.

Case XIV.—W. T., 26 years old; Russian Hebrew; Mt. Sinai Hospital, July 10, 1909. No history of lues. History of similar trouble in the left leg which was amputated in May, 1907, for gangrene of the third toe. There has been pain in the left calf for three months with coldness of the foot, followed by the development of a dry patch over the third toe. History of phlebitis of the veins of the right leg in Dec., 1908. He now has pain in the right leg interfering with walking. Physical examination: Typical erythromelia, evidence of phlebitis in the territory of the saphenous. Pathological examination of the amputated left leg showed the typical lesions of thromboangiitis obliterans.

Case XV.—M. G., 37 years old; Russian Hebrew. Aug. 9, 1909. No history of lues. One year ago migrating phlebitis of both lower extremities. Six months ago coldness of the right foot which has been followed by red discoloration of the forepart of the foot, associated with a feeling as if pins and

needles were sticking him. There have been cramp-like pains in the calf on walking for the past three months. The left leg is painful because of the presence of thrombosed veins, and cramps on walking. Physical examination: Right internal saphenous forms a hard cord. The left saphenous has evidently been recently thrombosed. Dorsalis pedis and posterior tibial arteries of both legs are pulseless. Marked ischemia on elevation, and erythromelia in the dependent position of both legs. Amputation of the right leg at the Sydenham Hospital, a portion of the posterior artery received for examination and the diagnosis of thromboangiitis obliterans made.

Case XVI.—H. R., 30 years old; Russian Hebrew; Mt. Sinai Hospital, Sept. 6, 1909. No history of lues. Seven years ago, onset with pain and numbness in the right calf on walking, relieved by short periods of rest. Six weeks later swelling and redness of the big toe with the formation of a trophic ulcer under the nail. Since then a number of ulcers have appeared and healed spontaneoulsy. Finally gangrene of all the toes of the right leg necessitating amputation in the upper part of the leg. The left leg has given him symptoms for eight weeks; the toes have become swollen and discolored at their tips; evidently about to become gangrenous. Physical examination: Gangrene of the big toe and marked edema of the whole foot. None of the vessels of the leg pulsate. Amputation of the left leg at the middle, Sept. 11. Pathological examination showed the lesions of thromboangiitis obliterans.

Case XVII.—D. F., 40 years old; Russian Hebrew, Nov. 7, 1909. Symptoms of intermittent claudication in the right lower extremity without trophic disorder. Left leg negative. Physical examination shows absence of pulsation of popliteal, posterior tibial, and dorsalis pedis. Marked ischemia and erythromelia. Clinical diagnosis: Thromboangiitis obliterans. No history of lues obtainable.

Case XVIII.—C. H., 25 years old; parents Russian Hebrews; Mt. Sinai Hospital, Dec. 23, 1909. No history of lues. Pain in the left leg on walking for about a year. Red discoloration of the foot for four months. Beginning ulceration of the third, fourth, and fifth toes. Physical examination: Ulceration of the third, fourth, and fifth toes, marked ischemia on elevation, and erythromelia in the dependent position. Left popliteal, posterior tibial, and dorsalis pedis arteries are pulseless. Progressive gangrene, making amputation of the leg necessary. Pathological examination shows lesions of thromoboangiitis obliterans.

Case XIX.—I. L., 35 years old; Russian Hebrew; Mt. Sinai Hospital, Oct. 1, 1906. No history of lues. Usual history. Amputation of the left leg at the mid-calf on Oct. 3. Pathological examination showed the usual lesions. July 1, 1907, readmission to the hospital for amputation of the right leg at the request of the patient because of intense pain. Dec. 15, 1909, readmission for necrosis of the right stump.

Case XX.—M. C., 24 years old; Russian Hebrew; Mt Sinai Hospital, March 18, 1908. No history of lues. Onset first on the left side, and a year later on the right. Spontaneous cure of the left leg. Feb. 12, 1910, gangrene of the big toe with the usual accompanying symptoms.

Case XXI.—A. K., 27 years old; Russian Hebrew; Mt. Sinai Hospital, Jan. 24, 1906. No history of lues. Admission for pain in the middle finger of the left hand, gangrene of the tips of the middle and fourth fingers of the right hand with spontaneous cure. Feb. 25, 1907, ulceration of the second toe of the left foot. Amputation below the knee. Readmission for necrosis of the stump. Gritti amputation Jan. 2, 1909, followed by healing. Pathological examination: Thromboangiitis obliterans. Dec. 30, 1909, gangrene of the tip of the little finger of the right hand and amputation of the finger. Feb., 1910, typical symptoms developing in the right foot.

Case XXII.—I. W., 48 years old; Russian Hebrew; Mt. Sinai Hospital, Dec. 25, 1909. No history of lues. Symptoms of intermittent claudication in the right leg for about two years. For six weeks pain in the big and little toes of the right foot and recently the big toe has become black. Physical examination: Gangrene at the tip of the big toe, marked ischemia in the elevated position, erythromelia in the dependent position. No pulsation in the posterior tibial or dorsalis pedis.

Case XXIII.—S. S., 40 years old; Russian Hebrew, Feb. 5, 1910. No history of lues. Trouble in walking for about a year. Evidences of migrating phlebitis in the territory of the right saphenous. Unable to walk because of pain in both feet, especially in the right. Physical examination: Marked erythromelia in the right foot; marked blanching on elevation, somewhat less marked on the left. The posterior tibial and dorsalis pedis arteries do not pulsate on either side.

Case XXIV.—S. W., 37 years old; Russian Hebrew, March 9, 1910. No history of lues. About a year and a half ago the big toe of the left foot began to pain him and showed a reddish discoloration. He had had some trouble in walking for about two and a half years because of cramps in the left calf. Four weeks ago an ulcer formed on the big toe of the left foot. Physical examination: The forepart of the left foot shows moderate erythromelia in the dependent position, and the nail of the big toe is being lifted off by an accumulation of serum. The right foot is also slightly red and swollen, and shows a number of fissures. Both feet become markedly blanched on elevation. The posterior tibial and dorsalis pedis arteries of both feet are pulseless; the right popliteal pulsates faintly, the left not at all.

Case XXV.—S. A., 35 years old; Russian Hebrew; Mt. Sinai Hospital, Aug. 11, 1903. No history of lues. Swelling of the great toe of the left foot about three years ago, followed by pain on walking ever since. For past two days severe pain with the development of a gangrenous patch on the dorsum of the left leg. Amputation. Pathological diagnosis: Thromboangiitis obliterans. March 15, 1907, amputation of right leg for gangrene. March 10, 1910, amputation of the left arm for gangrene of the fingers. Pathological examination: Thromboangiitis obliterans.

Case XXVI.—M. S., 48 years old; Russian Hebrew; Mt. Sinai Hospital, March 29, 1910. No history of lues. Typical history with the development of ulceration of the fourth toe of the left leg. Amputation three years ago. Six months ago symptoms in the right foot. Physical examination: Dry gangrene of the fourth toe; absence of pulsation in popliteal, posterior tibial and dorsalis pedis arteries.

Case XXVII.—J. R., 32 years old; Russian Hebrew, Sept., 1909. No history of lues. In 1894 he had pain in the left calf on walking. Two years

later an obstinate ulcer appeared which finally healed. He has been free from trouble since. Physical examination on Sept. 11, 1909, shows an absence of pulsation in all the vessels of both lower extremities; evidently a case of spontaneous cure with extensive obliteration of vessels without symptoms.

Case XXVIII.—H. F., 40 years old; Russian Hebrew; Mt. Sinai Hospital, Feb. 11, 1910. No history of lues. Usual history of intermittent claudication with the development of redness of the forepart of the left leg about four months ago. Physical examination: Dry gangrene of the big toe of the left foot, marked erythromelia, and blanching of the limb on elevation. Popliteal, posterior tibial, and dorsalis pedis of both legs are pulseless. Feb. 12, 1910, amputation of the upper fourth of the leg. Pathological examination; Thromboangiitis obliterans.

Case XXIX.—A. L., 45 years old; Russian Hebrew; Oct. 10, 1909. Pain in the calf of both legs for about seven years, which has become so much aggravated on the right side that walking is now impossible. Physical examination: absence of pulsation in the right dorsalis pedis and posterior tibial; on the left side the posterior tibial alone is pulseless. March 1, 1910, right foot found much paler than the left; the big toe is slightly cyanotic. Moderate ischemia on elevation and moderate erythromelia in the dependent position. The left leg looks practically normal.

REPORT BY DR. KALISKI.

Complement fixation tests for syphilis were made in the above twenty-nine cases. The regular Wassermann system and the Noguchi antihuman modification were applied in each case, while in fifteen of the cases, in addition to the above tests, the Bauer modification of the Wassermann system was also performed.

The tests were carried out according to the protocols of the originators of the above systems. In the Bauer test a slight modification was made in the cases lacking natural amboceptor or where this hemolytic agent was not present to the extent of two units, in that the deficiency was made up by the addition of a double dose of artificial amboceptor. Methyl alcoholic saturated solutions of pure lipoids obtained from syphilitic or normal liver or heart or from beef liver or guinea pigs' hearts by alcohol extraction and subsequent acetone fractionization were utilized as antigen.

As will be seen by reference to the above, the cases under consideration were examined at various times from June, 1909, up to June, 1910, each patient's serum being tested, together with a fairly large number of cases sent from the wards and clinic of the Mount Sinai Hospital for diagnosis. At each examination, therefore, besides the usual positive and negative controls necessary in every series of tests, there was a sufficiently large number of positive and negative cases to test the efficiency of the antigen extract.

It is of significance that in every one of the twenty-nine cases examined the reaction was definitely negative with all the tests applied. In two cases the reaction was repeated at intervals of one and three months, respectively, with the same outcome.

Inasmuch as mercurial treatment is able to influence the reaction, occasionally changing a positive outcome to a negative one, we have tried to ascertain to what extent this has been a factor. In thirteen of the cases there was absolutely no history of the patients receiving antispecific treatment during or prior to the course of the disease. Five of the patients did not know whether they had received any treatment of the above nature. Seven had been inmates of hospitals where it is possible that they received some medication, which may have been mercurial, although we could not determine this definitely. Four of the patients received mercurial treatment, although in none could this be said to have been thorough. Some of the patients had received varying amounts of potassium iodide from time to time. On the whole, it seems fair to assume that in only four of the cases could the treatment be considered a factor influencing the outcome of the reaction. In none of these patients did the course of treatment precede the examination of the blood within a sufficiently short space of time to influence it directly. Further, in only one of the cases was the treatment of so vigorous a nature as to be entited to be called "sufficient treatment," and thus possibly influence the reaction.

Let us for a moment look over the results of investigators, too numerous to mention individually, in the later stages of syphilis, for it is to the later period of this disease that we would refer thromboangiitis obliterans if it were a syphilitic disease. Bruck has collected the results of a large number of investigators showing 50 to 60 per cent. of positive reactions. With manifest lesions in the late stage of lues, and especially with lesions of the vessels, the results are apt to approach or even exceed the latter figure. In 867 cases of late latent lues, including those that had received treatment, with or without manifest lesions, the above-mentioned author reports 30.5 per cent. of positive results. In 660 cases examined in this country more recently, without manifest lesions, 55 per cent. were positive with the Wassermann system and 63 per cent. with the Noguchi method. In about 75 cases of treated and untreated tertiary syphilis, with and without lesions, examined at the Mt. Sinai Hospital during the past year, 60 per cent. were positive with the Wassermann system and 80 per cent. with the Noguchi. These cases include those that had received some treatment. Hoehne found in a study of over two hundred luetics that about one-third persisted in giving a positive reaction in spite of treatment.

It is evident from the above citations that in spite of treatment positive results may be expected in a fair proportion of the cases. Even energetic treatment is not always sufficient to dissipate the reaction in a positive case; and once negative, the reaction is apt to return in a certain number of the cases, especially with an exacerbation of lesions.

A negative result, we concede, cannot in any given case be construed as evidence of the absence of syphilis. Still from the facts adduced above it is evident that a certain proportion of positive results is to be expected in a series of cases of possible syphilitic origin. Inasmuch as not a single positive reaction was obtained in twenty-nine consecutive cases of thromboangiitis obliterans, it is fair to assume that this disease is probably not of luetic origin.

THE RELATIVE VALUE OF SYMPTOMS, PHYSICAL SIGNS, TUBERCULIN, AND THE X-RAY IN THE DIAGNOSIS OF TUBERCULOSIS.*

By HENRY F. STOLL, M.D.,
HARTFORD, CONN.
ASSISTANT PHYSICIAN TO THE HARTFORD HOSPITAL; PHYSICIAN TO THE TUBERCULOSIS CLINIC, HARTFORD DISPENSARY.

So voluminous is the literature pertaining to the early diagnosis of tuberculosis that I feel almost like apologizing for choosing so trite a subject. My excuse is, that while incipient cases are detected somewhat more frequently perhaps than a few years ago, at least in the larger cities, there are still many mistakes made in diagnosis. These errors are the result of not appreciating the full significance of the various physical signs and symptoms.

The incorrect diagnoses are of two varieties, the more common being the failure to recognize definite indications of the disease. The other mistake is the erroneous diagnosis of tuberculosis on insufficient evidence. As this latter error is not generally discussed, we will devote a few minutes to its consideration.

Two classes of physicians make this mistake. One comprises the very conscientious men who are thoroughly alive to the urgent need of the early detection of the malady and examine their patients with minute care, but with an eye for positive signs only. Totally disregarding the overwhelming negative evidence, they pin their diagnosis to a single sign. These are they who make tuberculous mountains out of benign molehills.

In the other class we find those physicians who, either because of insufficient time or laziness, do not make a careful examination, but rely upon one of the aids to diagnosis, failing to realize that these measures are aids to diagnosis only when considered with all the clinical evidence. There are many who do not appreciate that it takes from half an hour to an hour to obtain a history, make a careful examination, and give the necessary advice. Even then a second or third examination may be needed before an opinion can be given. Finally, it should be remembered that the absence of physical signs, like the failure to find tubercle bacilli in the sputum, does not exclude tuberculosis when the symptoms point to that diagnosis. When these two facts are universally understood, the day of early diagnoses will dawn. The physician who awaits the finding of tubercle bacilli in the sputum before hazarding a diagnosis of tuberculosis wastes invaluable time for which no subsequent activity and diligence on his part can atone.

In the short time allotted to this paper we can consider only a few of the more important physical signs and symptoms. The general appearance of the patient is very untrustworthy evidence, as Barnes[1] found that over 60 per cent. of his incipient cases appeared to be in good health.

Physical Signs.—Contrary to some statements, inspection ofttimes gives us information of the greatest value. While retraction at the apex suggests an old lesion, which may or may not be active, distinct lagging with diminished expansion of the apex is one of the most important signs we have of an active lesion. Turban considers it[2] "certain evidence of lung disease." In children it is occasionally due to enlarged bronchial glands. Tenderness to palpation seems more common in the acute than in the chronic cases, and while not present in the majority of patients, its occurrence has considerable significance. Lagging, tenderness, with possibly slight muscle spasm at an apex, almost invariably means an active lesion at that site. Tenderness over the upper thoracic spines, the spinalgia of Petruschky,[3] while not pathognomonic of tuberculous disease of the bronchial glands, is quite a constant sign in early cases with toxic symptoms. The point of maximum tenderness seems to be at about the fifth thoracic vertebra. Advanced cases do not present this phenomenon.

Dullness at the apex usually signifies a tuberculous lesion at that site. Several clinicians have demonstrated, however, that especially in children this dullness may be due to induration collapse at the apex, the result of obstructive nasal breathing from adenoids. Grancher,[4] and more recently Bing,[5] attribute this dullness to enlarged bronchial glands, which may or may not be tuberculous. Dullness over the fifth and sixth thoracic spines, and to the side of these vertebræ, is very suggestive of bronchial gland enlargement. To be of value percussion must be performed *very gently*, as the sense of resistance is of about as much significance as the character of the note obtained.

Auscultation is the most valuable of our clinical methods, but the practice of listening only for râles cannot be too strongly condemned. In auscultating, the character of the respiratory murmur should receive our first attention, all adventitious sounds being disregarded for the time being. The first change in breathing consists in a weakening of the respiratory murmur, which assumes a tremulous character, referred to as rude or ganular breathing. The presence of marked bronchovesicular breathing without râles at one apex, should make one examine the other apex with great care, as the more recent lesion will often be found there. Cogwheel respiration in the first and second interspaces on one side with faint breathing above the clavicle, is very suggestive of a lesion at the apex. Bronchial breathing and whispered bronchophony over the upper thoracic spines is usually indicative of enlargement of the bronchial glands.

We next seek for râles and they will often be unrecognized unless we have the patient cough at the end of expiration. The presence of râles over a limited area on several examinations suggests a tuberculous focus, especially when they are heard over the upper part of the lung. But râles at an apex may be due to other conditions. Koch[6] states that 15 per cent. of his patients with apical catarrh failed to react to tuberculin. Lord[7] has reported a few cases of influenza with persistent râles at the apex. If the lesion is tuberculous, one cannot say from râles alone that the disease is active. I have known them to persist for years after all symptoms disappeared. Do not think that I consider râles of little significance. When accompanied by symptoms, they are, perhaps, the most important single sign of tuberculous disease. Frequently, however, the diagnosis must be made in their absence. From râles alone one cannot diagnose clinical tuberculosis. We must not lose sight of the fact that there is a great difference between clinical tuberculosis, which gives symptoms and needs treatment and anatomical tuberculosis, which for the time being is not giving symptoms, and does not need treatment.

The physician with a good ear and poor judgment is almost as dangerous to the community as

*Read at the Annual Meeting of the Connecticut State Medical Society, New Haven, May 25 and 26, 1910.

the man who examines the lungs through the clothing and impressively tells his patient that he is "sound as a dollar." The former fills sanatoria with the nontuberculous; the latter, graveyards with consumptives.

Clinical History.—This is so important that the whole time allotted to this paper might well be spent in its discussion. Careful inquiry must be made as to the exposure to tuberculosis, either in the family, in business, or in social relations, bearing in mind that in some cases the infection comes from a tuberculous servant. The state of the health during childhood and adolescence must be carefully investigated, as not uncommonly the first symptoms appeared many years previously. We are apt to overlook the fact that tuberculosis may exist for years without completely disabling the person, or causing much lung destruction. The history of these individuals is punctuated with times of "running down," but owing to their resistance, or the mildness of the infection, the battle has been a draw. Two histories will illustrate this:

Case I.—Mrs. E. G., aged 44. When a child was never strong. At 12 was thin and pale and doctors feared she might "run into consumption." When 25 years old she ran down and had a bad cough the greater part of a year. Six and one-half years ago the patient had another hard cold, which terminated in a mild pneumonia. Following this, was told that her lungs were "weak." Each winter would have severe colds. For the few months before I saw her she had been running down and coughing slightly. A large part of her life she felt "dragged out" and tired, but she and her physician attributed it to a retroversion and laceration of the uterus. Notwithstanding that the infection was at least nineteen years old, she had only a slight lesion at both apices.

Case II.—Miss E. G., aged 32. As a child had poor appetite and was weak and delicate. Had bilateral pneumonia at 15 months; the infectious diseases, including whooping cough, in early life. At 16 had night sweats and a cough of such severity that she would get "black in the face." Recovered, and for two years was in good health; then she again began to cough, and the abdomen became swollen. Again recovered, but from the 20th to 22d year had a cough that necessitated taking hold of something to support herself during the paroxysms. Six years ago had ovary and appendix removed, and intestines were "said to be involved." The few months previous to my seeing her she had been fairly well, except for a slight cough, and extreme weariness. As she expressed it, she had been "chronically tired and lazy" as long as she could remember. Although of sixteen years' duration, her lesion was almost wholly limited to the lungs above the clavicles, the active process being at the left apex. The periodical hard attacks of coughing suggested bronchial gland involvement, and the physical signs and *x*-ray picture showed this to be the case.

A patient's statement concerning his past illness should never be accepted without going thoroughly into his symptoms at that time to determine whether he really had "malaria," "grip," or "nervous prostration," as the case may be. As to his present symptoms, one should inquire concerning cough, fatigue, spitting of blood, night sweats, lost weight, pain in the chest, anorexia, indigestion, dyspnea, and interscapular backache. Unless one have a special history blank, it is very easy to omit one or more questions, and by so doing the key to the diagnosis may be missed.

Cough and blood spitting are two symptoms which often send a patient to his physician, or to a throat specialist. No man doing special work has greater opportunity to further the early diagnosis of tuberculosis than the laryngologist. He who treats a chronic cough without first having the lungs declared sound by one proficient in chest examinations, is assuming a grave responsibility. Only recently I found advanced disease of the whole of the right lung with infiltration of the left apex in a patient who was receiving throat treatments for his cough. The laryngologist had examined the lungs and found them all right. On the other hand, I have detected a very early lesion in a number of patients who had been refused treatment by throat specialists till their lungs had been examined. The fact that the cough of tuberculosis may be temporarily helped by throat treatments quiets any suspicion as to the gravity of the condition.

The patient should be asked if he coughs until he gags or vomits. Though all patients with tuberculosis do not have such a cough, a very large percentage of those who gag or vomit have tuberculous disease of the lungs or bronchial glands. Professor Delafield used to say that pertussis and tuberculosis were the two diseases in which the patient coughed until he vomited. This occurs more frequently as an early symptom than blood spitting, and it has nearly as much significance.

While hemorrhage in the great majority of cases means tuberculosis, and should always be treated as such until proven otherwise, one may have blood-streaked expectoration from ruptured varicose veins in the post-pharynx and naves, and also from the unconscious sucking of the gums. I know a man who was a patient at one of the best sanatoria in this country for several months before it was ascertained that the blood he expectorated came from his gums. The diagnosis was made more difficult because of a positive reaction to the subcutaneous tuberculin test. Blood spitting from mitral stenosis is often mistaken for tuberculosis, one reason being the disappearance of the murmur when compensation is lost. The diagnosis must not be made hastily as both diseases may be present. Fatal hemorrhages have occurred from the erosion of blood-vessels by tuberculous bronchial glands when the lungs were free from disease.

A young adult, previously ambitious, who complains of a constant weariness should always excite our suspicion, especially if he has a rise of temperature and an unduly rapid pulse after moderate exercise.

Tuberculin.—The most widely used aid to diagnosis is tuberculin. While a positive reaction is specific and always signifies a tuberculous focus somewhere in the body, considered by itself, it by no means proves the individual to be clinically tuberculous. A focal reaction in lung, gland, or bone, as the case may be, proves the tuberculous nature of the lesion.

The subcutaneous test is the most reliable. Owing to the large number of severe reactions reported from the employment of the conjunctival test, this method is less extensively used than it was a year ago. It is, however, not without its advocates. From their observation of the results in a large series of cases, Haman and Wolman reported at the recent meeting of the National Association for

the Study and Prevention of Tuberculosis that they considered it a safe and very valuable diagnostic measure when used in suitable cases. They advocate a 1 per cent. solution of "old tuberculin." Though I have never had any bad results from its use, I discarded it about two years ago because of the ill effects reported by others. I have always felt, however, that most of these bad results were due in part to its use where it was clearly contraindicated and also to the employment of too strong solutions.

The skin test of Von Pirquet loses much of its significance as the age increases. Yet an early strong reaction in an adult with suspicious signs and symptoms, increases somewhat the probability of the condition being tuberculous. The faint reactions are very confusing, as they occur in many in good health, and also in a certain percentage of the patients that are going to do badly. I have seen several patients in whom the prognosis seemed good, but whose skin reaction was faint and evanescent, progress to a fatal termination in a few months. Wolf-Eisner's contention that the type of reaction will often foretell the outcome has considerable to substantiate it. A negative skin test in a suspected case does not absolutely exclude tuberculosis, though it makes the diagnosis unlikely. The subcutaneous test is sometimes positive when the von Pirquet test is negative.

To sum up, we have in tuberculin a diagnostic aid of real value if it is used in conjunction with the symptoms and physical signs. But the physician who would arrive at a diagnosis by merely scratching the skin and dropping thereon some tuberculin, might as well settle the question by the toss of a coin.

X-ray Examination.—The *x*-ray, which has proven so valuable in many lines of work, is of much assistance in the diagnosis of pulmonary conditions. The negative must not only be perfect, but the interpretation thereof is of value only when made by one who has had a large experience in this particular field as it is the most difficult of all *x*-ray work. Incipient cases that have been carefully examined come to postmortem but rarely, so that much more can be learned by the comparison of the physical signs and *x*-ray findings in a series of early cases than by the autopsies of advanced cases.

Dr. Arthur C. Heublein and I have studied over fifty cases in which I had previously made a clinical diagnosis. To insure an unbiased opinion, the plates were studied by numbers, not by names. In one case the physical signs indicated a lesion from the right apex to the second interspace (inner third), but the radiograph showed involvement of the greater part of the lung. In a second case, a lesion at one apex was suspected, but the *x*-ray showed both to be involved. In two cases where history and physical signs pointed conclusively to an early process, the *x*-ray failed to show it. In the remaining cases, most of whom had very early lesions, the *x*-ray and the clinical diagnosis agreed.

The *x*-ray is the greatest stimulus to careful diagnosis we have, and there is no better way to ascertain one's diagnostic ability—or limitation—than to compare his physical signs with the *x*-ray plate. In deep-seated lesions, especially of the lower two-thirds of the lung, the *x*-ray will sometimes demonstrate a lesion that does not give physical signs. When the involvement is slight, it may be necessary to make several plates before a diagnosis can be given.

In conclusion, if we are to detect incipient tuberculosis, we must inspect, palpate, percuss, and auscultate our patient. More than that, we must question him, and question him at length. The physician who cannot or will not devote at least half an hour to this consultation should refer his patient to one who will, as an incomplete examination gives the patient an unwarranted sense of safety.

Our eyes, fingers, and ears are like the scouts of an army who bring to headquarters information of varying importance. The observation of one would appear to show the urgent need of immediate retreat, but that of the others would make this action seem unwise. Only after all the reports have been carefully weighed is it decided which is the most expedient course to pursue.

PERSONAL OBSERVATIONS ON THE EHRLICH-HATA 606.

By ABR. L. WOLBARST, M.D.,
NEW YORK,
CONSULTING GENITOURINARY SURGEON, CENTRAL ISLIP STATE HOSPITAL; VISITING GENITOURINARY SURGEON, PEOPLE'S HOSPITAL; GENITOURINARY SURGEON, BETH ISRAEL HOSPITAL AND WEST SIDE GERMAN DISPENSARIES; PROFESSOR OF GENITOURINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC.

For some weeks past I have had the opportunity of observing at close range the workings of the new Ehrlich-Hata preparation familiarly known as 606. In the laboratory of Professor Ehrlich, at Frankfort, where experiments are still in progress on animals, and in most of the skin and venereal clinics of Berlin the new preparation has been freely used, with the result that some 3,000 cases treated with it have already been reported.

It appears to be too early, as yet, to make any positive statement on the value of this preparation in syphilis and parasyphilitic conditions, but there can be no doubt, in view of the results thus far obtained, that a great step forward has been made. The reports made by those who have given the remedy the largest trial, particularly Wechselmann, Alt, Michaelis, and Kromayer, carry with them a measure of enthusiasm that seems nothing less than extravagant, but when one sees the patients and the progress they have made under the new treatment, this enthusiasm seems more than justified.

The principal work is being done by Wechselmann at the Rudolph Virchow Hospital in Berlin. He has treated over nine hundred cases, having been among the first to receive the remedy from Ehrlich. Wechselmann's technique is the one principally used in the European clinics, but there are two other methods of administration that are growing in popularity, namely those of Alt and Kromayer. The growing favor of these methods lies not in any appreciable increase of efficiency, but rather in the greater simplicity of their preparation.

It is not the purpose of this paper to discuss the preparation of the solution used, but rather to offer a review of the methods of injecting the remedy and the results obtained. I have had the opportunity of studying about 250 cases, and have seen about 35 injections given at the various clinics. The results may be tabulated as follows:

As to Dosage:—The dose administered varies from 0.4 gram to 0.6, and in some cases to 0.8 and even 1.0 gram, but the general tendency is in favor of 0.6 as the safest and most effective dose for a male adult of normal size and weight. In women 0.5 is used, and in children 0.025 is given. Professor Ehrlich has expressed the opinion that the proper dose in proportion to the body weight is about one gram per 60 to 70 kilograms of body weight.

Site of the Injection:—It may be given intravenously or intramuscularly. The former method was tried by some experimenters, but nearly all have given it up in favor of the intramuscular injection. For the latter some employ the site of the buttocks while others prefer the muscles of the back, immediately under the lower angle of the scapula. My observation leads me to the belief that the gluteal injection is the one that will be commonly adopted in the course of time.

Method of Injection:—The solution is freshly prepared with the greatest aseptic care, immediately before it is to be given. The site chosen is sterilized with either iodin or ether and alcohol, and the solution is injected in a manner similar to that of the mercury preparations. Care is taken that the solution does not enter the blood vessels, unless one of the soluble methods is used. After the injection has been given the needle is quickly withdrawn, moderate pressure is made over the injected area, the skin is again painted with iodin, and is covered with a piece of sterile gauze, which is held in place by a strip of adhesive plaster. The patient is put to bed and kept there for four or five days, and longer if necessary. Kromayer divides the dose and injects half of it into each of the buttocks. He believes this diminishes the risk of infiltration and abscess formation.

After Effects:—In the vast majority of cases the injection is quite painless. In a few that I saw the pain was very severe, and lasted with diminishing severity for three or four days. The paraffin injection, used by Kromayer and Lesser, seems to be absolutely without pain. In an old woman with a gumma of the ankle, who had been injected in the back by Michaelis, there was considerable subsequent pain, not only at the site of the injection, but also down to the region of the buttocks and along the arm and forearm of the injected side. Most of the patients stated that they felt very little or no pain at any time.

For some time after the injection an infiltrate remains, similar to that often seen after the injection of salicylate of mercury, but it soon disappears. Occasionally this infiltrate becomes acutely inflamed, and in some cases an abscess forms with necrosis of the surrounding tissues. I saw three or four such cases. It is difficult to say whether this complication is due to the preparation itself or to an external infection due to faulty technique, but I am of the opinion that the latter is the more likely cause. The painful infiltrate is affected favorably by the application of heat; sometimes cold is more effective. At all times it should be treated along surgical lines.

I believe that those who are injected in the back are more liable to severe pain and abscess formation than those injected in the buttocks. I did not see a single case of abscess in the buttock.

A fair proportion of patients develop some fever after the injection, the temperature often rising to 100° to 102° F., but this lasts only a few days and then drops to the normal. Occasionally the rise in temperature appears on the fourth or fifth day, and remains for several days.

In a small proportion of cases an exanthem, covering the entire body, appears soon after the injection and remains for some time. This is ascribed to the rapid absorption of the arsenic. As soon however, as the arsenic is eliminated, these symptoms pass off.

Effect on the Primary Lesion:—The primary lesion heals very rapidly in most cases, sometimes disappearing entirely within one to two weeks after the injection. Within a few days a softening of the lesion and distinct evidences of healing set in; the infiltrate, however, remains for some time after the visible signs of the sore have disappeared.

I have seen a marked improvement within 48 hours after the injection, in a few cases, and in others it has taken as long as two or three weeks for the lesion to disappear. The remedy seems to offer the possibility of an earlier removal of the initial lesion than by any means hitherto known, except excision. The locality of the lesion does not interfere in any way with the result.

Effects on the Secondary Lesions:—Secondary lesions occasionally disappear within several days after the injection, but usually it takes about two weeks for all the secondaries to disappear. The glandular enlargement in the neck remains long after the mucous patches have passed off. It is at times startling to observe the wonderful improvement in these early cases.

Effects on Late Manifestations:—In many cases gummata that have resisted mercury and the iodides for years have disappeared in from three to six weeks, and have not since recurred. In some cases the improvement was very slow and in others the remedy seemed to have had no apparent effect, but these cases were very exceptional.

In parasyphilitic conditions and in nerve lesions of syphilitic origin the remedy has been tried by Konrad Alt and others, with promising success. The results are not so brilliant in these nerve cases, but the experimenters express themselves as being hopeful of success. At the annual gathering of German physicians and naturalists at Königsberg, whither I had the privilege of accompanying Professor Ehrlich, Professor Alt, in the discussion on 606 said, in this connection: "For the nerve specialist and psychiatrist the most important feature of the new Ehrlich-Hata remedy is to be found in the increased possibility of furnishing an effective prophylactic against the severest diseases of the nerves and the mind, namely, tabes and general paralysis." This utterance is in accord with the commonly expressed view that the function of the new remedy will be to prevent late lesions of the nervous system rather than to cure them.

In Inherited Syphilis:—Wechselmann has already reported a number of cases of infants treated with the new remedy with considerable success. I saw a number of these young patients, and in some instances the result of a single injection seemed nothing less than marvelous. Others, on the other hand, did not seem to respond to the remedy so

well, while still others, very few in number, showed no response whatever. There can be no doubt, however, of one thing: The results in these cases warrant the dictum that every case of infantile inherited syphilis should be treated with "606," if it is hoped to save the infant's life.

Recurrence:—A slight proportion of cases seem to recur after six to eight weeks. Possibly, the dose in these cases was insufficient. At any rate, I have seen a very few cases (not more than 5 per cent. of the total number) in which a recurrence of the roseola or the mucous patches took place after they had disappeared. In these cases a second injection has been very effective. Wechselmann has just reported a number of cases in which reinjections of 606 have been made with success. He believes that the injection may be repeated with safety within one week, but it is better to wait three or four weeks before repeating.

Effects on the Wassermann Reaction:—In the majority of cases the reaction changes from positive to negative after six to eight weeks, that is, when all spirochetes have been destroyed. If any of these survive the injection the reaction is apt to remain positive, even though the clinical manifestations of the disease have disappeared. Most observers seem to confirm the view that 606 tends to destroy the spirochetes, and to that extent the change from positive to negative takes place; but the effect varies in individuals. In the majority of cases, with a dose less than 0.6 gm., it takes from 30 to 60 days for the reaction to become negative. Herxheimer of Frankfort believes that three-fourths of all cases become negative after 50 days. The strength of the dose undoubtedly has an important bearing on the Wassermann reaction, *i.e.* the stronger the dose the earlier and more certainly will the reaction change from positive to negative. Another observation that is commonly noted is that the reaction is more apt to change from positive to negative in primary cases than in late lesions. This observtion has been confirmed by Pinkus of Berlin.

Effect on the Body Weight:—A gain in weight is a very constant effect in cases injected with 606. With few exceptions the patients show an appreciable gain, sometimes of many pounds, in addition to which the general well-being and appetite of the patient are materially improved. Some patients who entered the hospital as veritable skeletons have gained 20 to 30 pounds in the course of a month or six weeks after the injection.

A few illustrative cases observed in the various clinics will be of interest:

Case I.—Woman with old lues, saddle nose. For several months has had a large gummy tumor of the upper lip with infiltration of the entire surrounding tissues, which made it almost impossible to open the mouth. Speech and swallowing were very difficult. In spite of long continued treatment by mercury, the gumma continued to grow larger. Twelve hours after the injection of 0.5 gm. a decrease in the swelling began, and on the next day the patient was able to open the mouth wider than it was possible for many weeks. In a few days there was continued healing and subsequent recovery.

Case II.—Man, saddle nose, foul-smelling ozena and headache, which made it impossible for him to work, for many months. Had been treated with mercury and potassium iodide for a long time without effect. Three days after the injection of 0.6 gm. headache was better; six days later there was hardly any smell from the nose. Recovery.

Case III.—Man with mucous patches of the mouth; had just finished a course of mercurial inunctions without effect; 24 hours after the injection, the patches were hardly noticeable, and in 20 days they had disappeared.

Case IV.—Girl, 19; waitress. Presented a deep ulceration on the tongue and mucous membrane of the mouth. She had just received 20 bichloride injections, and though the exanthem had disappeared, the patches remained. Was given 0.3 gm. and three days later the patient was sent home practically well. Wassermann remained positive for five weeks and then became negative.

Case V.—Man, very much emaciated, the whole body covered with papules and ulcerous syphilides; mucous patches in the mouth and tongue, and necrosis of the tonsils. The patient had received 30 injections of Hg without benefit. Was given 0.6 gm. In fifteen days all the symptoms had disappeared, and the patient had gained 12 pounds. Wassermann remained positive.

Case VI.—Girl 21, marked roseola with broad necrotic condylomata on the vulva and anus, mucous patches on tongue and mouth. Duration eight weeks, no treatment. Spirochetes numerous. Was given 0.4 gm. Two days later marked improvement, no spirochetes found. Thirteen days later patient was discharged well. Wassermann remained positive.

Case VII.—Girl 20, entered hospital in very poor condition; she was very much emaciated and could neither speak nor swallow. There were many broken down papules on the face and forehead, rupia on the limbs. Tonsils, uvula, and larynx much destroyed with ulcerations. Duration six months; had been treated with mercurial inunctions and injections, and with KI. Was given 0.5 gm. The next day swallowing became easier; a few days later the voice became normal and recovery was so rapid that fourteen days after the injection the patient was sent home practically cured.

My observations lead me to this general conclusion: The new 606 preparation exerts a marvelous effect on a large proportion of the cases in which it is used properly; in some cases its effects are not so striking, but the results are, nevertheless, very good; in a few cases the result is negative. We may safely say that if this preparation is not a complete specific for syphilis and allied conditions, we have in it apparently the most potent and effective remedy that science has yet produced for the treatment of these diseases.

REPORT OF THREE CASES TREATED WITH ANTIGONOCOCCUS SERUM.*

By M. ZIGLER, M.D.,

New York,

Instructor in Genitourinary and Venereal Diseases in the Post-Graduate Medical School and Hospital, Assistant Dermatologist Lebanon Hospital, O. P. D.

The subject of my paper this evening is a report of three cases treated with antigonococcus serum. I cannot, however, go on to the report of these cases without a few prefatory remarks on the history and preparation of this serum. We are indebted to Dr. John C. Torrey of Cornell University, whose researches in this particular field of serum therapy made the introduction of antigonococcus serum possible. The serum as used to-day is prepared accord-

*Read at a meeting of the Bronx Medical Society, May 11, 1910.

ing to his method from the blood of rams that have been treated with gradually increasing doses of dead and live cultures of the most virulent strains of gonococci.

I shall quote from Torrey's article on agglutinins and precipitins in antigonococcus serium. He says: "It has been proven that the gonococcus belongs to a heterogeneous rather than to a homogeneous family, in fact it may be divided into several groups each raising agglutinins which are specific for its own group." It is for this reason that we use a polyvalent serum.

Willaim T. Belfield in "Progressive Medicine" says "the great value of both sera and vaccines in gonorrheal lesions of serous membranes (*i.e.* gonorrheal rheumatism so-called) is absolutely confirmed, while the failure of both to definitely improve gonococcus infections of mucous membranes seems supported by further evidence." Herbst thinks that most failures and reoccurrences in serum treatment of arthritis arise from either failure to remove the infection from the genital tract or insufficient dosage of treatment.

We shall now go on to the consideration of these three cases.

Case I.—Mrs. M., age 30, American, came to my office April, 1908, with the following history: Married three years, she has a baby two years old. Immediately after birth of child she complained of burning on urination and profuse purulent discharge, which continued about three months. About ten days after the onset of discharge patient began to complain of pain, stiffness, and limitation of motion in small joints of both hands, followed by pain in the wrists, shoulders, and left hip. She had been under antirheumatic treatment for four months without any improvement. In fact she became progressively worse; pain in the wrist and shoulders had become so severe and constant that she was unable to sleep and was obliged to have assistance in order to dress herself and comb her hair. Her best weight was 140 pounds. At present she only weighs 105 pounds—a loss of 35 pounds in two years. Physical examination at that time showed that she was poorly nourished, pale, and markedly anemic with hemic murmur at the base. Chest otherwise normal. Fingers showed thickening and limitation of motion of the joints of the middle and proximal and middle and distal phalangeal articulations. Smear from urethra and vagina negative. Treatment.—For the three months of April, May, and June, 1908, patient received huge doses of aspirin, later sodium salicylate, and still late potassium iodide, during which time strict antirheumatic diet was ordered. Practically no improvement was noted. Electricity tried, faradic, and galvanic, for several weeks with same result. Patient became discouraged and discontinued her visits to the office for about four months during which time her symptoms remained the same. On her return I made the diagnosis of gonorrheal arthritis and decided to give antigonococcus serum. The administration of the serum was as follows: The injections were all given into the subcutaneous tissues of the arm, by means of a large hypodermic syringe similar to the antitoxin syringe used in diphtheria. First injection October 23, 1908. One c.c. of a polyvalent serum from which there was no improvement. Five days later a second injection given, 1 c.c., with no improvement. Three days later a third injection, 2 c.c. of serum. Within one hour patient's arm on side injected became very painful and swollen from the shoulder down to the finger tips. This continued for about six hours and then disappeared. For the first time slight improvement in the shoulder and hipjoint noted. Seven days later a fourth injection, 2 c.c., which was also followed by marked swelling of the arm injected and in addition a generalized urticaria developed. The latter subsided in 72 hours. Marked improvement noted in all the joints affected commencing in three hours after the injection and continuing until about 24 hours before the next when all the symptoms returned, but not as severe as they were originally, in other words a 48-hour respite of symptoms. Fifth injection three days later, 2 c.c. of serum, results about the same as above; that is marked improvement for 48 hours, then slight return of symptoms. Patient now begins to feel hopeful. Sixth injection, 2 c.c. Patient for the first time had no return of pain since the last injection, although there was a four-day interval between this injection and the previous one. Three days later seventh injection, 2 c.c., with practically no pain. Patient begins to notice some improvement in ability to flex and extend fingers. Motion in shoulder also more free. Eighth injection three days later, same as above; patient feels stronger and better in every way. Ninth injection, 2 c.c.; patient felt so much improved that she neglected treatment for seven days with the result that on the fifth day symptoms returned with pain especially severe in the shoulders and hip; but she admits that the pain is in no sense a relapse, for although she was uncomfortable during the day, yet she was able to sleep well. Tenth injection, 2 c.c. Since the last treatment patient has felt very comfortable. She noted relief from pain within a few hours after the administration of the serum. In December patient received five injections. There was so marked an improvement in the symptoms shown that I decided to cut down the number of injections for the following months. For each of the following three months the patient had three injections. During this time there was absolutely no return of symptoms, marked improvement in motility of joints affected, with general condition much better. Only one injection given in the month of April. In May two were given. The end of May, 1909, patient was discharged cured. One month ago I received a communication from this patient stating that she is in good condition, so much so that she is able to do all her own housework. She sleeps well, appetite good, and has gained 20 pounds.

Case II.—Mr. H., aged 58 years; married, business man. Had gonorrhea 10 years ago. Came to the office of his physician on April 20, 1909, with acute gonorrhea. Smear taken at that time showed the diplococcus of Neisser. He was put under treatment immediately with antiblenorrhagics and locally injections of argyrol, 5 and 10 per cent. Nine days later he developed acute arthritis of the right wrist, which became red, hot, and painful. He received large doses of salicylate of sodium with no improvement. Four days later the left knee became involved, and he was obliged to take to bed. Salicylates were continued for another week and then discontinued and Bier treatment instituted. The doctor used an ordinary Esmarck bandage about 2 inches wide, applied night and morning for several days. He started with half-hour sessions and gradually increased length of application. The result of this treatment was also unsatisfactory. This was the state of the patient when the doctor consulted me for therapeusis. Taking into considera-

tion the history and duration of this case with inefficiency of the treatment instituted covering a period of 16 days, I advised antigonococcus serum. Accordingly on that day patient received 2 c.c. of polyvalent serum. No improvement noted. Following day he received another injection of 2 c.c. Joint pains remained the same. Third day received a third injection of 2 c.c.; slight improvement followed for the first time. Fourth day received fourth injection of 2 c.c. Patient much better, sitting up in bed, with marked diminution of pain and swelling. Twenty-four hours later received a fifth injection, 2 c.c. Improvement continued. One day later received the sixth and last injection, 2 c.c. Wrist normal and no pain in knee joint. Some exudate, however, still present. Seven days later, wrist was absolutely normal, knee almost so and patient was able to attend to business. The serum injections caused no untoward reaction in this patient.

Case III.—Mr. X. American, single, age 31 years. Had gonorrhea four years ago, which lasted eight months. No complications. Three years ago a second attack, which was followed in four months by pain in the sacrum, left knee, heel, and shoulders, of such character that patient spent many restless and uncomfortable nights. At times pain became so severe that he was obliged to go to bed for three or four days of every month. These symptoms, together with anorexia and loss of weight, persisted for two years and failed to respond to antirheumatic and all other treatments. Treatment was as follows: Patient received nine injections of antigonococcus serum, 2 c.c. at three-day intervals. After the third injection there was slight improvement in the joint symptoms. At the completion of the treatment, the affected joints showed absence of pain but poor motility. The treatment was followed by massage resulting in complete recovery.

It is rather difficult to draw conclusions from so few cases. You will notice, however, that cases I and III were injected at intervals of three to four days, being chronic ones. While case II, being acute, received injections at 24-hour intervals in an attempt to minimize destruction of joint tissue by the action of the gonococcus. There is absolutely no doubt in my mind when I think over the usual protracted and maiming course of these arthritic cases that this treatment is absolutely specific and that there is no excuse for any physician allowing this class of patients to go on into the crippled stage without first trying this serum. According to Dr. Torrey no case of gonorrhea complicated by arthritis, endocarditis, epididymitis, or pleuritis should be treated without serum in conjunction with usual methods.

1097 Forest Avenue.

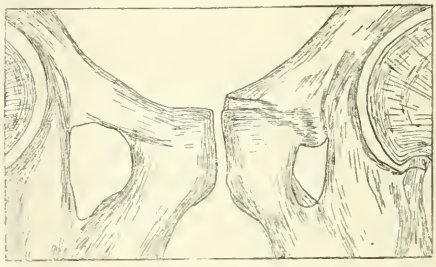
A FRACTURE OF THE PUBIC BONE.

By TRUMAN ABBE, M.D.,

WASHINGTON, D. C.

Fractures of the pelvis as part of a general crushing accident are recognized and described in our text books, but the following case of fracture of a single bone in the pelvis is rather unusual on account of the slightness of the injury and the light weight of the patient. In place of the usual fracture of the neck of the femur that we get in older patients with a fall on the hip, in this case the femur was not injured, but the pelvis suffered.

Mr. B., white, 74 years of age, weight 120 pounds, and in good, active health, on October 15, 1909, while crossing the street encountered an automobile and two motorcycles. He dodged all these, but in turning slipped on a banana peel and fell, striking on his left tuber ischi. Unable to rise, he was carried to his home and put to bed, where he was unable even to turn over in bed. Two days later I saw him in consultation with Dr. Keech. He was unable to turn over in bed or to move the left leg fully at the hip. Thigh flexion to 45° was possible, but beyond that great pain was felt in the adductor muscles; full extension was possible and comfortable. The functions of the leg were normal. No ecchymosis or sign of displacement or abnormal position were visible. Moderately heavy percussion on the heel caused no pain, but heavy percussion gave pain in the pubic region and in the adductor muscles. Partial motion of the leg showed the flexion at the hip to be limited as in the active motion to about 45°, and abduction also to be somewhat limited. Pressing the great trochanters together caused pain and a similar crowding together of the iliac crests gave the same pain. A separation of the iliac crests also gave the same pain. The left tuber ischi was tender, but only with



Fracture of the Pubis.

a dull soreness, not the acute tenderness of the anterior region. Pressure on the symphysis pubic caused acute, cutting pain, accentuated about one and a half inches to left of the median line. This seemed to be the starting point of all the pains. There was no bladder or urethral trouble further than a slight irritability which the patient thought no more than common in cool weather, or when lying down. We made a diagnosis of fracture of the pubic bone and strapped the pelvis with a girdle of adhesive plaster and applied a firm bandage, giving marked relief and ability to turn in bed. Two days later he began to spit blood-specked mucus, and moist râles appeared throughout the bases of his lungs. Strychnine, 1/30 of a grain three times a day, and some deep-breathing exercises repeated every hour cleaned up that pulmonary congestion in forty-eight hours, and no further signs of pulmonary trouble developed.

At the end of six weeks the patient was allowed to put his weight on his feet for a few minutes, and a week later he was walking around with a cane. The unsteady walk, with his feet far apart, soon disappeared and the gait six months later was as good as ever. At twelve weeks he came to the office and we took an *x*-ray picture of the pelvis, which confirmed the diagnosis of fracture of the left pubic bone. In the drawing traced from the plate the line of fracture is seen to run from the symphysis pubis to the upper margin of the obturator foramen. There is a displacement of the upper fragment upward by about one-fourth of an inch at the symphysis.

New York, October 15, 1910.

EXAMINATIONS AND PRIZES.

For some considerable time the question of the value of examinations and the giving of prizes for those who pass such at the head of their class has been a subject for discussion. There are many who hold that the examination as a test of knowledge is to a large extent valueless and the awarding of prizes is likewise vanity and vexation of spirit. An address dealing with the matter was delivered by Dr. S. Squire Sprigge, editor of the *Lancet*, at the opening of the medical session at St. George's Hospital, London, on October 1. As for examinations Sprigge expressed the view of most who have studied the point when he said that no system of professional training can be conceived without examinations although there were many who were skeptical with respect to their utility. In short the examination system is so welded into our methods of early education that it would be difficult to provide an efficient substitute. As a matter of fact, the crux of the problem is with regard to what is meant by education. If by education is meant that part of the training which ends with the final examination and the granting of the diploma, it is easy to prove that success in examinations does not necessarily augur success in life, and it also shows that the examination system and the giving of prizes is wrong. But if one regards the final examination as only a stage in the progress of education then the prize and examination system must be considered from another standpoint. As Sprigge puts the situation: "Those who look upon education as a short race, starting in the case of the medical man with his school curriculum and ending with registration, and consider the professional life that follows as a long but completely separate race, another item on the race card, will hold on the soundest of sporting grounds that the man who wins the sprint need not win the staying contest. And in support of this self-evident proposition we have quoted to us the instances of the various failures in after life of men who vastly flattered their friends and tutors at the outset of their careers." This, however, does not prove that examinations and prize giving are useless, for it would be but a narrow-minded way of passing judgment. Examinations, then, and prizes are useful in so far as they are evidence that the individual has been so trained that he is in the position to reap the benefits which should accrue to him and to the public of the later tuition which will proceed throughout his life. Thus "examinations are a means to this end and no more; prizes are an incentive to the end and no more."

Still, there should be limits to examinations and to the number of subjects which are nowadays introduced into the medical student's curriculum. It is practically impossible to crowd into the four, five, or six years of a medical course the multiplicity of subjects with which the student is at present plied. It goes without saying that with some of the subjects he can have but a bowing acquaintance and the temptation to cram without assimilating the matter is great in order to make a good showing at the examinations. There is little doubt that examinations are overdone and the material given the student is too varied and heavy for his digestion. In fact, it is not so much the examination system that is in fault, but it is the abuse of the system against which the protests should be directed. In the opinion of Sprigge the prize system is to be deprecated to this extent that students are too greatly considered in this respect and that it would be a wiser policy to provide lectureships, readerships, fellowships, and professional chairs for the teachers rather than scholarships and exhibitions for the students. The speaker pointed out that while prizes are required for both scholars and teachers the needs of the instructed always appear in Great Britain to appeal much more powerfully to donors than the needs of the instructors, a position which seems not to obtain in the progressive educational centers of the United States. It really comes to this: How can we expect students to be properly taught unless their instructors have acquired the knowledge to impart to them, and how can instructors acquire this knowledge unless means of attaining it is freely afforded.

The most pregnant part of the address lay in the final phrases, in the postscript so to speak, and was a plea for honest work. That is to say that the student resolves "that, come what may, he will understand what he sees, what he hears, and what he reads before he proceeds to the next stage in his education." It is obvious that, with the large number of subjects before him, he cannot expect, perhaps, to learn more than the rudiments of any one subject, but he should learn these rudiments thoroughly. The temptation is great to scamp the most difficult parts, yet it should be borne in mind that even if a student who pursues the course is fortunate enough to pass his examination he is then ill prepared for the practice of his profession and must spend valuable time in laying the foundation which he should have laid before he passed, otherwise he will not only not be a success but a source of danger more or less to the community.

There is one point on which Sprigge did not touch when discussing the question of students and prizes and that is the reason why so many brilliant prize winners are comparative failures in the battle of life. The brilliant man who learns with facility frequently forgets as easily. His facility is fatal; he learns so quickly that his mind does not retain the matter sufficiently long to be of practical use to

him. On the other hand, the plodder learns slowly and with difficulty, but the very difficulty impresses the subject so firmly in his mind that he retains it and thoroughly assimilates it. There appears to be, at the present time, unanimity of opinion as to medical examinations and subjects being overdone in all civilized countries and Dr. Sprigge did well to call attention to the matter in his able address.

HYPERSOMNIA OR PATHOLOGICAL SLEEP.

Disturbances of sleep form one of the most striking groups of clinical phenomena. Not alone in diseases of the central nervous system of organic and functional origin do these aberrations of sleep prevail, but also in conditions of disturbed metabolism and in infectious processes. The study of the physiology of sleep has for a long time engaged the attention of physiologists and psychologists, and many theories have been propounded in explanation of its origin. Basing his speculations upon the theory of the toxic origin of sleep, which theory has had many adherents, A. Salmon contributes to the *Revue de Médecine*, September 10, 1910, an interesting paper on the physiological mechanism underlying the production of hypersomnia. This condition is to be distinguished from somnolence, or the tendency to fall asleep, which frequently has a pathogenesis distinct from hypersomnia, although they may coexist. According to the toxic theory, sleep is an expression of the intoxication of the nerve centers by the effete products of metabolism. Salmon holds that these substances do not affect the nerve cells directly. During sleep the latter are engaged in the task of elaborating and storing up the nutritive reserve material residing in the chromatophilic substance. The toxic products of metabolism are neutralized by the internal secretions of certain glands, whose hormones at the same time have a stimulating action upon the reparative powers of the nerve cells. This hypothesis is apparently in accord with the clinical observation of the intimate relation existing between disorders of sleep and alterations in the hypophysis, thyroid, choroid plexus, and other ductless glands. Hypersomnia is one of the most characteristic symptoms of affections of the hypophysis. Insomnia has been described as one of the common manifestations of insufficiency of the hypophysis, responding effectively to the administration of pituitary extract. The indirect effect of toxic substances producing sleep is explained as follows: An increased production of toxic substances causes at first a hyperfunction of the hypophysis or of other ductless glands, with a resulting increase in the normal sleep.

Hypersomnia is described as one of the most characteristic signs of mild forms of thyroid insufficiency, and may occur independently of the usual manifestations of cachexia strumipriva. Myxedematous subjects are generally apathetic and frequently have veritable attacks of narcolepsy. Occasionally the somnolence of myxedema is followed by insomnia, which fact may be attributed to the functional exhaustion of the hypophysis resulting from its hyperactivity, and to a secondary intoxication of the nerve centers. Frequently hypersomnia is associated with a function disturbance of the genital glands. The menopause is generally accompanied by a tendency to increased sleep and to obesity. Hypersomnia is a frequent symptom in the slow intoxications of gastric, intestinal, hepatic, and renal origin. Obesity and diabetes are often associated with a hypersomnia of toxic origin. This is also observed in certain intoxications of infectious disease. This is strikingly seen in influenza, in which the increased tendency to sleep is followed during convalescence by hyposomnia and insomnia. In cerebral syphilis hypersomnia is frequently observed. The hypersomnia of tumors of the brain represents one of the most interesting chapters of neuropathology. It has been described as one of the most characteristic signs of tumors of the frontal lobes, likewise of tumors of the base of the brain, hypophysis, third ventricle, and infundibulum. It is significant that those tumors residing near the floor of the third ventricle present the same symptoms observed in lesions of the hypophysis, namely, hypersomnia, obesity, mental troubles, etc. One of the principal symptoms of mountain sickness is an irresistible desire to sleep. This is to be attributed to passive cerebral hyperemia, which also explains the hypersomnia of those who work in compressed air. The sleep crises occurring in insolation are relieved by epistaxis. Passive congestion of the brain also explains the deep sleep following the epileptic seizure. Increase of sleep is frequently noted as one of the manifestations of adenoid vegetations of the nasopharynx. This may be explained by the observation of Civalleri of the presence in the posterior part of the pharynx of a gland having the same properties as the hypophysis cerebri. Adenoid vegetations have ever been regarded as aberrant hypophyses. Hypersomnia is one of the frequent manifestations of sphenoidal sinusitis, which is probably to be attributed to the contiguity of the sphenoidal sinus to the hypophysis, and to the fact that suppuration in either of these may be communicated to the other.

Salmon concludes that sleep plays a useful rôle in the intoxications affecting the nerve centers, and even in its morbid states represents a defensive reaction of the organism against these intoxications. The danger of toxic hypersomnia resides not in the sleep but in the intoxication; the effort should be not to combat the sleep, but to seek to control the causes that tend to prolong it. The treatment would therefore consist, for example, in the administration of thyroid, pituitary, or ovarian extracts, the regulation of diet in the intoxications of gastric, intestinal, hepatic, and renal origin, and the surgical treatment of nasal affections.

ANAPHYLAXIS AND IDIOSYNCRASY.

As was to be foreseen,, what has commonly been known as idiosyncrasy is coming more and more under the domain of anaphylaxis. This is notably evident in drug idiosyncrasies, which made up a large percentage of such phenomena. Drug idiosyncrasies undoubtedly depend chiefly on some defect of the blood in forming neutralizing

antibodies. It should not be difficult to discriminate between anaphlaxis proper, and the peculiar psychic phenomena induced by certain odors, sights, etc. There are also food idiosynerasies which belong to neither group, as seen in cases where sugar behaves as an active cathartic, acting almost as soon as tasted and swallowed. Not even drug idiosyncrasies necessarily depend on anaphylaxis. When atropine irritates the conjunctiva outright or glycerin similarly irritates the skin, the supersensitiveness must be local in character.

Klausner (*Münchener medizinische wochenschrift*, Sept. 20, 1910) has for some time been occupied in studying the relationship between medicinal rashes and anaphylaxis. He first tested on animals the serum of men supersensitive to tuberculin and iodoform, and found that even the supersensitiveness could be conveyed to the animals. Two patients developed marked supersensitiveness to iodoform which was shown to extend to potassic iodide. The serum of these men after supersensitiveness had developed was inoculated into six guinea pigs, while controls received only normal sera. The so-called anaphylactic serum acted fatally, causing death very rapidly, as if by shock. The animals all received minute doses of iodine after the preparatory injection of anaphylactic serum. A question of interest is the following: Had patients who developed iodine idiosyncrasy at a given time ever previously taken iodine, especially with exhibition of idiosyncrasy? This could be shown in one case, but doubtless cannot be held to apply universally.

The author's article is very brief and sketchy, as if written chiefly in the interest of priority. There can be no doubt that the subject opens up many probabilities. Anaphylaxis which is transferable to animals will of course come to be distinguished from drug-rashes not thus transferable. The problem naturally has considerable bearing on serotherapy, as through its solution it may be possible to overcome some of the difficulties in the management of cases in which supersensitiveness to remedies is known to exist or may be presumed to exist.

A Skin Reaction in Cancer.

While waiting for the discovery of a specific cure for cancer, which may be nearer than one dares hope, the general consensus of medical teaching, with few exceptions, is that the only salvation for the bearer of a malignant growth is in the earliest possible operation. This, of course, depends upon early recognition, but cancer is notoriously insidious in its beginnings, and by the time the symptoms are sufficiently pronounced to warrant operation, especially in the case of internal growths, it is usually too late, and any operative interference is then as likely to scatter the seeds of disease as it is to bring permanent relief. Any method therefore that promises to facilitate the diagnosis of a malignant growth in its earliest stages is to be welcomed. Writing in the *American Journal of the Medical Sciences* some time ago, Elsberg, Neuhof, and Gint of the Mt. Sinai Hospital, of this city, described a skin reaction which they obtained in several cases of carcinoma from the subcutaneous injection of human red blood-cells. The reaction depends upon the hemolytic action of the serum of the subject of malignant disease. This action has been observed *in vitro*, but it is often so feeble that it is difficult to determine its presence, and Elsberg accordingly conceived the idea of bringing the red cells into immediate contact with the serum of the cancerous patient *in vivo*. Carrying out this idea, the authors of the paper instituted a series of experiments on cancerous and normal individuals, injecting under the skin a suspension of crushed erythrocytes in saline solution. When a reaction occurred it began to show itself in about five hours after the injection and gradually increased in intensity during the next two or three hours. It appeared in an irregularly oval, slightly varied, reddish area, measuring from 2 to 5 cm. in length and 1 to 3 cm. in width, not infrequently surrounded by a whitish areola. It persisted for a variable period of time, usually from six to twelve hours after the injection. Six hundred and eighty-four injections were given to 432 individuals with quite uniform results. In 89.9 per cent. of the cases in which a reaction occurred there was a positive diagnosis of cancer, and in 94.3 per cent. of the cases in which no reaction occurred it was possible to exclude malignant disease.

News of the Week.

Death Rate in Cities.—The city of St. Paul, Minn., is credited with being the healthiest city in the United States so far as the figures of the Census Bureau for 1909 have been computed. Five cities of 100,000 population or over, San Francisco, Louisville, Minneapolis, Omaha and Memphis, are not included in the list since the census returns of 1910 have not been announced. In St. Paul the death rate for 1909 was 11.4 per 1,000 of population, while that in New Orleans was 20.2, the highest for the year. Other cities having a low death rate for the year are Columbus, O., 13.4; Cleveland, O., 12.8; Detroit, Mich., 14; Indianapolis, Ind., 14.3; Kansas City, Mo., 14.4; Rochester, New York, 14.4; and Chicago, 14.6. The death rate of New York City was 16 per 1,000 of population, and of Philadelphia, 16.4.

Free Dental Clinic.—Philadelphia is making provision for the care of the teeth of its school children by establishing a free dental clinic for those too poor to receive private treatment.

Henry Phipps Institute.—Dr. Charles M. Montgomery and Dr. Isaac Brown have been added to the teaching and clinical staff of the Henry Phipps Institute for the Study and Treatment of Tuberculosis; Dr. J. B. Carnett has been elected consulting surgeon, Dr. T. B. Holloway, consulting ophthalmologist, and Dr. D. J. McCarthy, consulting neurologist. Dr. Samuel G. Dixon, State Commissioner of Health, and Dr. Joseph Neff, Director of Public Health and Charities, have been appointed ex-officio members of the Advisory Council of the Institute.

Changes at University of Pennsylvania.—After seventeen years of service, Provost Charles Custis Harrison of the University of Pennsylvania has tendered his resignation, and the matter has been

referred to a special committee for consideration. Mr. Harrison has for thirty-five years been a trustee of the University.

Dr. J. William White has resigned from the John Rhea Barton Chair of Surgery after thirty years service in the University in various capacities. Dr. White has largely interested himself in the development of athletics in the University, and had much to do with the establishment of Franklin Field.

Epidemic of Twins.—Two hundred twin babies were born in Chicago during the first nine months of 1910 as against 140 during the entire year 1909.

Fire Near Hospital.—A fire in the rear of the Eastern District Hospital in Williamsburg, N. Y., recently, caused some alarm among the forty patients of the institution, but the coolness of the nurses and attendants prevented any serious consequences.

Births Increase.—For the month of August, 1910, according to the report of the State Department of Health, there were 11,207 births in New York City and 6,050 deaths. The native population of the city thus increased 5,157 in that time. Manhattan Borough is credited with 5,794 births and 3,054 deaths, while Brooklyn Borough had 3,661 births and 1,955 deaths. For the entire State the total number of births was 18,049 and of deaths 11,998, making a net gain in the native population of the State of 6,051. During the month there were 103 suicides, 41 homicides, and 734 deaths by accidents.

The New York Homeopathic Medical College opened on October 4 with a reception in the college building. Addresses were made by Mr. Melbert B. Cary, President of the Board of Trustees, Dr. John E. Wilson, and Dr. Royal S. Copeland, Dean of the College. The college begins the year with an increased enrollment, the incoming class being the largest in its history.

Public Drinking Cups Barred.—On October 1 the regulation of the Massachusetts State Board of Health forbidding the use of public drinking cups went into effect in Boston. Under the new rules no such cup can be used in any public park, street, or way; in any building or premises used as a public hotel, theater, public hall, or public school; in any railroad car or station, steam or ferry boat. In many places the sanitary bubbling fountains have been installed.

Radium Reduced.—The price of radium is now quoted as only $2,100,000 per ounce, instead of $3,000,000. The total amount of radium in the world is said not to exceed a quarter of a pound. In Paris and London radium banks have been established, the substance being loaned to scientists and physicians. In some cases the charge has been as high as $200 for 100 milligrams for a single day.

Drought and Typhoid Fever.—A number of cases of typhoid fever occurring in Westchester County, N. Y., have been ascribed to the drought which has prevailed in New York City and its vicinity, a drought which is the longest in the recollection of the oldest inhabitant. During July, August, and September only 3.79 inches of rain fell, the normal fall for these months being about thirteen inches. In the smaller towns, without adequate provision for the storage of water, this has caused great inconvenience, and has been a source of danger since many persons have been driven to use ponds and brooks hitherto avoided as polluted.

Cholera Situation.—The death from cholera of a steerage passenger from Naples while under observation at Quarantine, New York, and the development of the same disease in a fireman on a vessel from the same port have increased the vigilance of the health authorities, and the Public Health and Marine-Hospital Service is working in conjunction with the State officials. A five days' quarantine for all immigrants from cholera infected ports may be enforced. Many new cases have been reported in Rome and Naples, although in Russia the situation is improving.

The "Index-Lancet."—With the October issue the *Index-Lancet* of Kansas City, Mo., closes its thirty-two years of existence, and passing into new hands will appear under another title after consolidation with the *Medical Herald* of St. Joseph. First issued in 1880 as the *Index*, under the editorship of Dr. F. Dickman of Fort Scott, Kan., the journal, later known as the *Index-Lancet*, has had a successful career guided by able hands. In the new phase of existence, Dr. Charles Wood Fassett of St. Joseph will assume the rôle of Editor-in-Chief, assisted by Dr. S. Grover Burnett of Kansas City. Dr. John Punton, the retiring editor, and Dr. O. L. McKillip will also be members of the editorial staff.

Straus Milk Depot.—Several thousand persons attended a mass meeting at Cooper Union, New York, on the evening of October 8, and passed resolutions commending the work done by Mr. Nathan Straus in the maintenance of the milk depots for the distribution of pasteurized milk. At the same time public officials were urged to use their powers to carry on and develop the work if Mr. Straus persisted in his intention to withdraw his name. Among the speakers were Dr. Abraham Jacobi and Dr. W. A. Evans, Commissioner of Health of Chicago.

Dr. Louis Wickham of Paris will deliver an address (in English) on the subject of "Radium-therapy," at the New York Academy of Medicine, 17 West Forty-third street, on Thursday evening, November 3, at half-past eight.

Removal Notice.—Dr. Ross McPherson announces the removal of his office to 20 West Fiftieth street, New York.

Dr. Charles J. Bartlett has resigned the office of Medical Examiner of New Haven, Conn., and Dr. M. McR. Scarborough of the Yale University Medical School has been appointed in his place.

The Associated Physicians of Long Island will hold a meeting in the New Opera House at Oyster Bay on Saturday, October 15. Mr. Theodore Roosevelt will address the meeting at the opening session at three o'clock.

New York and New England Association Railway Surgeons.—The twentieth annual session of the New York and New England Association of Railway Surgeons will be held at the Hotel Astor, Broadway and 44th street, New York City, on November 3 and 4, 1910, under the presidency of Dr. L. M. Bingham of Burlington, Vt. Dr. John B. Deaver of Philadelphia will deliver the Address on Surgery on November 3, at 12 o'clock. A cordial invitation is extended to railway officials, railway surgeons, and to the medical profession to attend this session of the association. The secretary is Dr. George Chaffee, 338 47th street, Brooklyn, N. Y.

The Des Moines (Iowa) Pathological Society at a meeting held on September 23 elected the following officers: *President,* Dr. J. T. Priestley; *Vice-President,* Dr. F. A. Ely; *Secretary and Treasurer,* Dr. L. T. Piter.

The Society of Insurance Medical Officers was organized recently, at Chicago, with the following officers: *President,* Dr. Allison Maxwell; *Vice-Presidents,* Dr. Calvin H. English, Fort Wayne, and Dr. Stephen S. Werth, Chicago; *Secretary,* Dr. Edgar R. Hawley, Chicago; *Executive Committee,* Dr. William F. Milroy, Omaha; Dr. C. W. McCloud, St. Paul; Dr. Joseph Johnson, Chatanooga; Dr. Russell M. Young, Des Moines; Dr. M. M. Lairy, Lafayette. The purpose of the society is: "To establish an organized center of thought and action for the advancement of medical knowledge appertaining to life insurance by personal intercourse of its members, presentation of papers, discussions, and such other methods as may from time to time be found desirable."

The Indiana State Medical Association, at its annual convention at Fort Wayne on September 29, elected the following officers for the ensuing year: *President,* Dr. F. C. Heath, Indianapolis; *First Vice-President,* J. N. Hurty, Indianapolis; *Second Vice-President,* Dr. A. S. Dickey, Tipton; *Third Vice-President,* Dr. J. P. Salb, Jasper; *Secretary,* Dr. C. N. Combs, Terre Haute; *Treasurer,* Dr. David Stevenson, Richmond.

The Beaufort County (North Carolina) Medical Society was formally reorganized on September 30, when the following officers were elected: *President,* Dr. D. T. Tayloe; *Vice-President,* Dr. H. H. Hunter; *Secretary,* Dr. H. W. Carter.

The Michigan State Medical Society, at the closing meeting of the annual convention at Bay City, on September 29, elected the following officers: *President,* Dr. C. B. Burr, Flint; *Vice-Presidents,* Dr. C. T. Southworth, Monroe; Dr. Henry Kremers, Holland; Dr. A. B. Simonson, Calumet; Dr. A. L. Spalding, Hudson. It was decided to hold the 1911 meeting in Detroit. The Committee on the Relation of the Michigan State Medical Society to the University of Michigan reported that the University Board of Regents had agreed at its June meeting to suspend free treatment, medical and surgical, at the University hospitals in the cases of those persons who are able to pay.

The American Roentgen Ray Society at its annual meeting in Detroit elected the following officers for the ensuing year: *President,* Dr. Percy Brown, Boston; *Vice-Presidents,* Dr. Walter C. Hill, Cleveland; Dr. Willis Manges, Philadelphia; Dr. A. C. Skinner, Kansas City; *Secretary,* Dr. F. H. Baetjer, Baltimore; *Treasurer,* Dr. Charles F. Bowen, Columbus. Dr. Brown, who is well known in *x*-ray work in this city and New England, is the youngest member ever elected to the highest office in the gift of this society.

The International Pure Milk League, recently organized by a number of women in New York, was incorporated in the County of New York on October 7. The objects of the league are "to foster and encourage the production, distribution, and consumption of pure milk and pure food generally; to foster and promote the common interests of producers, dealers, and consumers of milk, and all other articles of food; to foster and promote methods of cleanliness in the handling of milk and all other articles of food from the producer to the consumer throughout the civilized world; to foster and promote local and foreign organizations of similar purpose with or without the league as a central or parent body."

Obituary Notes.—Dr. Jacob Hinson Miller, formerly of Boston, Mass., a graduate of the Hahnemann Medical College of Philadelphia in 1886, a member of the American Institute of Homeopathy, and the Boston Homeopathic, Massachusetts Homeopathic, and West Jersey Homeopathic Medical Societies, died suddenly at Saratoga, N. Y., on October 5, aged 45 years. Dr. Miller was formerly attending ophthalmic surgeon to many of the homepathic hospitals and dispensaries of Boston.

Dr. George Little of Tamaqua, Pa., a graduate of the medical department of the University of Pennsylvania in the class of 1884, city health officer, county out-door physician, and deputy coroner, died at his home, on October 3, aged 49 years.

Dr. Carey Kennedy Fleming of Denver, Col., a graduate of the Chicago Medical College in 1886 and of the New York Post-Graduate School and Hospital in 1889, professor of abdominal surgery and gynecology in the Denver and Gross College of Medicine, gynecologist to the State and County Hospital, the Mercy Hospital, and St. Joseph's Hospital, a member of the Colorado State and Denver County Medical Societies, and the Denver Academy of Medicine, died suddenly of apoplexy at his home on September 23, aged 47 years.

Dr. Clarence F. Tillman, formerly of Goldfield, Nev., a graduate of the College of Physicians and Surgeons of San Francisco in 1902, died at St. Luke's Hospital in San Francisco on September 25 of appendicitis, aged 32 years.

Dr. Benjamin F. Redshaw of Curran, Ill., and Dr. H. C. Ganaway of Decatur, Ill., were instantly killed on October 4, when two trolley cars collided head-on at Rickerson Curve, Ill. Dr. Redshaw was a graduate of the Northwestern University Medical School, Chicago, in 1899. Dr. Ganaway was a graduate of the Meharry Medical College of Nashville, Tenn., in 1902.

Dr. John Somers Buist, a retired physician of Charleston, S. C., a graduate of the Medical College of the State of South Carolina in 1861, a surgeon in the Confederate Army during the Civil War, and formerly professor of surgery in the medical college and a member of the South Carolina Medical Association, died at his home after a long illness on September 29, aged 71 years.

Dr. Jean P. Rottot of Montreal, Canada, a graduate of the University of the Victorial College in 1847, for many years dean of Laval, died at his home on September 28, aged 85 years.

Dr. Peter E. Richmond of Mt. Pleasant, Mich., a graduate of the Medical Department of McGill University, Montreal, in 1873, and a member of the American Medical Association, died suddenly on September 28.

Dr. Abijah I. Beach of Renton, Wash., a graduate of the Medical Department of Western Reserve University in 1856, died at his home after a long illness on September 24, aged 74 years.

Dr. Watson W. Gailey of Ashland, Ill., a graduate of the Philadelphia College of Medicine and Surgery in 1863, died on September 27, after a long illness, aged 68 years.

Dr. Whitfield S. Coursen of Oak Ridge, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1848, died at his home on October 1, aged 86 years.

Correspondence.

THE RELATION OF QUININE TO ECTOPIC PREGNANCY.

To the Editor of the Medical Record:

Sir: I do not think that an apology for this letter is necessary, for the custom of self medication with quinine, especially in malarial districts, is so prevalent that it should be discouraged as far as possible. Quinine is indicated in one disease—malaria—for its specific action on the malarial organisms. What other therapeutic properties it may possess as a tonic, antipyretic, etc., are surpassed by other remedies.

Quinine being a protoplasmic poison with a specific action on cells having ameboid movements, it may also arrest the movement of the ciliated epithelium, and so interfere with the physiological action of the ciliated cells in the Fallopian tubes, the function of which is supposed to be to create a current which carries the ovum from the ovary to the uterus. If this ciliary movement is arrested the impregnated ovum may implant itself at some other place than in the uterus ,and so give rise to an ectopic pregnancy. I know of two cases of ectopic gestation where no etiological factor could be found except that the patient was taking quinine at the time gestation ought to have taken place.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

POSITION OF SCHOLARSHIPS IN MEDICAL SCHOOLS.—EHRLICH'S NEW REMEDY, "606."—MEDICAL LIBRARY ASSOCIATION. — NOTIFICATION OF BIRTHS.

London, September 23, 1910.

With the approach of the new session there is a renewal of the anxieties of teachers and other officials of the medical schools as to the prospect of new entries and the inducements they can offer to intending students to select the respective institutions for fulfilling the curriculum. Among the inducements prizes of various kinds are offered by most of the schools. The best are scholarships tenable for a part or the whole of the curriculum and of otherwise varying values. The regulations affecting these scholarships have often been subjected to criticism and discussion, with a view of removing some of their defects. It has happened more than once that a smart student, or one *au fait* at examination tests, has sat for and succeeded at more than one of these trials, and so been able to choose at which school he would carry out his education, consequently holding them up, so to say, while making up his mind. The confusion thus produced is perhaps of less importance than the exemplification of an undesirable competition between collegiate institutions devoted to the same work. Amalgamation of the scholarships has again and again been suggested as desirable. In some cases financial difficulties may be reckoned on, but as to many others there is a free hand for the authorities. A considerable step in this direction has, in fact, been taken by the formation of the Intercollegiate Scholarships' Board. This body has just been holding an examination, on the results of which no less than twenty-three entrance scholarships or prizes will be awarded in University, King's, St. George's, and Westminster colleges and hospitals. The Women's Medical School is also a partaker in this scheme, and the board is quite willing to extend its work to all other medical scholarships.

Up to this year the divergent dates at which the several examinations were held were not altered, though it must often have been pointed out that an arrangement to hold all on the same day would prevent a candidate sitting at more than one. Now that the Intercollegiate Board has gone so far, perhaps a more complete amalgamation may follow in due time. With the example of the medical societies before the several authorities they will not despair of overcoming difficulties if they are convinced that combination is desirable.

"What do you think of 606?" That is the question which is sure to be put in any chance conversation between doctors here. It is only natural that a preparation originated by Ehrlich and endorsed by numerous observers in Germany and France should occupy our attention, especially when it claims to neutralize the poison of so fell a disease as syphilis. The preparation is not yet on the market, but the professor has freely supplied it to almost any one connected with venereal hospitals or with a reputation as a syphilographer. Quite a number of his confrères report cases in which the medicament seems to have acted as an immediate antidote to the syphilitic poison, restoring patients to health in a few days, and that in all stages of the disease. It is said the remedy will not be available in the drug market until Ehrlich has collected 20,000 cases from professional observers. In the meantime, the public is being regaled with sensational statements in newspapers. The reporter seems as ubiquitous on the Continent as here. Both German and French lay papers have devoted articles to "606" with descriptions of its alleged marvelous influence in conditions we have been accustomed to consider should only be described in professional journals. Our own papers have followed suit, and now the *Times* has opened its columns to telegrams and articles on the new treatment. Some talk of this as an advance in journalism and pooh-pooh the notion that any disease should be excluded from public discussion. I think the majority of medical men—certainly nearly all I have spoken with on the subject—condemn this attitude, though the few who support it are remarkably enthusiastic in their plea for press liberty.

At the London Hospital the remedy is being tried and I hear favorable reports of difficult cases. At the Lock Hospital, too, I am told that it is getting a fair trial. Neither of these institutions report serious disadvantages, though severe pain and infiltration at the site of injection has often been referred to, and some observers have noticed rise of temperature and symptoms distinctly attributable to arsenic, such as vomiting, etc. No one need be surprised at this, considering that the remedy contains 4½ per cent. of that poison, and the dose recommended is from 0.3 to 0.6 gram. Still, the idea of so absolutely specific an antidote as this is represented to be, clearing the system rapidly of an organic poison, is so attractive that, having the testimony of such able observers as to its powers, we can only wait patiently the reports from our own hospitals, until the remedy becomes accessible to all practitioners.

The Medical Library Association has been formed with the object of bringing together those interested in medical literature and medical libraries.

It is proposed to maintain an exchange for the distribution of duplicate copies, to increase existing facilities for reference work and to encourage the study of the history of medicine. Professor Osler has presided at some recent meetings to promote these objects, when papers were read by the librarians of the Royal Colleges and the Royal Society of Medicine.

Much annoyance has been caused by some local authorities in their attempts to carry out the act for the notification of births. They provide post cards to the doctors and midwives, and look to the former to see that they are used. They have even tried in one case to fine a doctor who, however, was able to show that he had told the midwife that either she or the father must notify, so the magistrate dismissed the summons and gave the doctor 5 guineas costs. The act lays the duty of notfication on the father, if resident in the house, and on anyone in attendance on the mother at the time. The difficulty really arises because legislators, as usual, made no provision for payment to the notifier. Many doctors feel aggrieved that they should be required to fill up certificates and transmit them, without any recognition of the service. The lawyers who abound in parliament take care that their own profession shall not be asked to witness a document without payment. But the doctor is constantly exploited for the State, as well as by various persons, and they think a little passive resistance desirable. Certainly it seems more reasonable for the father to be held responsible. If the State thinks notification desirable there are ways of obtaining returns without oppressing the profession. But the act is left for local authorities to adopt, or not, as they please, so it is scarcely a national concern.

Progress of Medical Science.

Boston Medical and Surgical Journal.

September 29, 1910.

The Plastic Surgery of the Ovaries and Tubes. W. C. Seelye, Worcester, Mass.
Post-Operative Pneumonia Without Mortality in Two Thousand Consecutive Surgical Operations at the Free Hospital for Women. W. P. Graves, Boston.
An Analysis of Seventy-two Cases of Pneumothorax. J. B. Ayer, Boston.

Plastic Surgery of the Ovaries and Tubes.—W. C. Seelye emphasizes the plea for more abdominal operations in the pelvic organs in cases of severe dysmenorrhea, and the importance of a classification as an aid in determining the mode of procedure in a given case for operation on the ovaries and tubes.

Post-operative Pneumonia in Surgical Operations.—W. P. Graves in an analysis of two thousand consecutive surgical operations arrives at the following conclusions: (1) Post-operative lung complications occur somewhat more frequently and are more fatal in cases previously septic or desperately sick or in the aged and feeble. (2) Operative shock, method of administration, length of time of the anesthesia, age of the patient, unless extreme, physical type of the patient, bad behavior under ether, wound sepsis, pulmonary embolism, do not seem to bear any constant relationship to the causation of post-operative pneumonia. (3) Post-operative pneumonia and bronchitis occur with great constancy during the cold weather months, and are rare during the summer months. (4) Preexisting foci of infection in the lungs are almost invariably lighted up or aggravated by operations under ether anesthesia. (5) The following theory of causation is suggested by the writer. Most of the cases of post-operative lung complications are caused by the lighting up or the aggravation of preexisting focal infection. (6) Many post-operative pneumonias might be avoided by a more careful and more expert preoperative examination of the respiratory tract.

Pneumothorax.—J. B. Ayer states that tuberculous cases comprised 69 per cent. of all cases of pneumothorax at the Boston City Hospital in twenty-eight years. Most were young or middle-aged men, and most had a recent history of less than six months' illness. The left side was most often affected. Pain and dyspnea were the most common symptoms at onset. The treatment was for the most part that of the fluid present; the prognosis was anything but encouraging. Autopsy showed cavities in most of the cases. Pneumothorax occurs most frequently in the side of a rapidly advancing process, where adhesions are either absent or friable. It may follow a long-standing empyema, by establishing a pleuropulmonic fistula or other means as yet not understood. Operative treatment in these cases is frequently permanently successful. One case is reported as resulting from subphrenic-intrathoracic abscess, and one from echinococcus. In traumatic cases the fluid develops rapidly; the air does not, as a rule, last long, and is probably of no serious import. *X*-ray examination has rendered diagnoses more exact, has qualified prognosis, and has explained the effect of treatment.

The Importance to Physicians of the New Employer's Liability Law. J. J. Moorhead, New York.
Twilight Talks by the Doctor. G. F. Butler, Chicago.
Bubonic Plague in Ground Squirrels. G. W. McCoy, San Francisco.
Scarlet Fever. J. Sobel, New York.
Aconite. J. Knoti, Dublin.
The Modern Brown Bread Pill. J. J. Buzzell, Brooklyn.

The Importance to Physicians of the New Employer's Liability Law.—Dr. John J. Moorhead describes the law enacted in New York State, and operative September 1, 1910, compensating employees injured while at work in certain trades, the nature and conditions of which involve extraordinary risks to the life and limb of workmen engaged therein. In case of loss of life the dependents receive a sum equal to twelve hundred times the daily earnings of the workman, in no event more than $3,000. Where the injury results in total or partial disability the workman receives a weekly payment equal to 50 per cent. of his average weekly earnings, not to exceed $10 a week, or extend more than eight years from the date of accident. Instead of the above the employee may elect to submit his case to a court and jury. Any workman entitled to receive weekly payments under this act is required, if requested by the employer, to be examined by a physician or surgeon provided and paid for by the employer, at intervals not oftener than once in six weeks. It is unfortunate that no official medical court of last resort is provided in case of dispute as to the extent or period of disability. The law is inadequate in that it does not provide for a physical examination preliminary to employment to discover latent defects, of which the subject may be ignorant, but which later may be ascribed to an occupation accident. Examples of such are hernia and defects of sight and hearing. To obviate the foregoing, employers or insurance companies will insist on a physical examination as a prerequisite to employment, with reexamination at yearly or other designated intervals. This may have an important economic effect in disqualifying certain workers for ailments not of themselves incapacitating, but which in the event of an accident might be ascribed thereto. This disqualification will fall with greatest frequency on workers past middle life, and at a time when wages are most necessary. Before granting a certificate of physical capacity the examination should embrace all that a life insurance medical certificate requires, and also special investigation of sight and hearing.

After receipt of injury the prognosis would depend upon the manner of receipt, technical nature, and extent of injury, the individual, the treatment, and the occupation. The compensation law would aid physicians in the care and treatment of the injured, by abolishing financial worry in the patient.

Twilight Talks by the Doctor.—Dr. George F. Butler discusses the interpretation of the baby's cry. The cry of discomfort is a pitiful wail, not as feeble as the cry of fretfulness, nor as strong as that of pain. The cry of hunger sounds much like the cry of discomfort, with an added tone of impatience. The cry of fretfulness is weak, plaintive, sometimes nasal in quality, and indicates general ill feeling without actual pain. The cry of pain is loud and vigorous, and in children over three months old is accompanied with tears. When a child cries out sharply and stops quickly, producing suppressed or choked cries, one should think of pleurisy as a possible cause of the symptoms.

Bubonic Plague in Ground Squirrels.—Dr. George W. McCoy states that the importance of ground squirrel plague is due chiefly to the fact that during the past two years the disease has been found among the squirrels in several places in California. It was noted that in several cases of plague occurring in Contra Costa County the victims were squirrel hunters, and it was suggested that squirrels might have been the source of infection. Experiments were conducted, and it was found that squirrels were quite susceptible to the infection. In Los Angeles the disease among the squirrels was detected through the fact that a typical case of plague developed in a boy who had been bitten by a sick squirrel. Prompt measures of squirrel extermination were inaugurated and carried out. Over 90,000 squirrels have been examined, and over 300 have been found infected. In infected localities the infection ran all the way from 1 in 1,000 to as high as 1 in 10. A purulent or caseous bubo is present in the majority of cases and is sometimes the only lesion. The plague bacillus isolated from infected squirrels is on the average somewhat less virulent than that isolated from rats and from men. There is a partial immunity among the squirrels in those localities where plague has prevailed for several years. Since plague was discovered among ground squirrels about a dozen persons have contracted the disease under circumstances that pointed conclusively to squirrels as the cause.

Scarlet Fever.—Jacob Sobel says that this disease ought to be on the wane, considering the activity of the Department of Health. But this is not the case. This is partly due to the fact that parents will not be convinced that very mild cases can be scarlet fever. These cases are the greatest carriers of contagion. Dogs and cats are also dangerous carriers of the disease. School inspection is a potent means of reducing contagion to a minimum. Too much stress has been laid upon the exfoliation; in some cases the main source of infection is some discharge from the nose, throat, and ear. Epidemics of scarlet fever have been traced to the milk supply. Incomplete isolation is a dangerous factor. Cases occurring in the colored race aid in the spread of the disease more through lack of recognition rather than because of failure to report. The author details various measures that would tend to check the spread of the disease.

Aconite.—John Knott concludes his elaborate study of this drug.

The Modern Brown Bread Pill.—J. John Buzzell states that the placebo has failed to receive its just share of credit for wonders worked, and describes its numerous indications.

Post-operative Complications in Acute Secondary Glaucoma.—D. Forest Harbridge gives the clinical notes of this and of two other unusual cases.

The Bookkeeping of Humanity.—J. N. Hurty states that the importance of vital statistics to the family, to the state, and to medicine can hardly be overestimated. The physician, the representative of the science of medicine, is, except in instances, the only member of society who can supply information in regard to causes of deaths and the presence of infectious diseases. As it is of very great importance to the family that its births, deaths, and cases of infectious diseases be legally recorded, and as the family presumably pays for the physician's services, the physician, therefore, should not consider his services fully performed nor that he is entitled to his fee until the certificates which are of such great importance are duly made. And again, the physician should remember when reporting vital statistics that he is giving obedience to the statutes of his State, on which he depends for protection; that he is protecting the helpless; that he is doing a general good, and that he is serving the science of medicine.

Poliomyelitis.—H. M. McClanahan, from an analysis of nearly one thousand cases of this disease occurring in Nebraska during the summer of 1909, concludes that it is an infectious disease. The evidence that it is contagious is accumulating. The only safe procedure is to treat it as we would measles or scarlet fever, namely, isolate the patient. We should realize that it is a general disease, that it may involve any part of the nervous system, that the bulbar type is usually fatal, and that our treatment should be directed toward prompt and efficient elimination

Ophthalmology in Preventive Medicine.—H. Woods discusses three phases of this subject, namely, prevention of blindness from infectious diseases and accidents, prevention of eye deterioration by violation of ocular hygiene, and prevention of remote lesions through recognition of early ocular symptoms of systemic disease. In the last of these the rôle of ophthalmology in preventive medicine means cooperative medicine. It means that if we view the eye from the standpoint of its own function this function is often affected by conditions beyond the oculist's power to diagnose or cure; that if ametropia be present, the physician may work in vain to relieve remote symptoms till the oculist helps him; that if the oculist appreciates the meaning of persistent functional disorders, a rigid pupil, seemingly unimportant muscular paresis, he may save his patient from dreadful consequences by asking his brother internist to aid him; that the problem of saving sight is not one which concerns the oculist alone, but is one which demands honest introspection from the physician and effort to educate his patients in the views which medical progress has taught us.

Metabolism and Mouth Disease.—H. R. Harrower concludes that we have conclusive evidence that in the study of the urinary acidity we have something of more than ordinary importance. The relation of this syndrome of findings—acidemia evidenced by a hyperacid urine, intestinal toxemia by indicanuria, and decreased metabolic activity by the frequent low urea index and general re-

duction in the total solids—to mouth-disease, is quickly found. It is safe to say that a majority of patients suffering from pyorrhea are acidemics, and the most conclusive feature of this work is that therapeutic measures calculated to reduce the acidemia and eliminate the toxemia have a decidedly beneficial effect on the pyorrhea.

Antityphoid Inoculation.—G. H. R. Gosman states that this has been so successful in reducing not only the death rate but also the number of cases of typhoid fever, that the United States Army is now using it and advocating its use. Up to June 1, 8,510 people have been inoculated by U. S. Army medical officers, and there have been but few severe reactions to the inoculation. There has not been a single case of typhoid in any one whose vaccination was completed, while among the unprotected there have been over 200 cases in the same period of time. The vaccine used is taken from a typhoid culture which is grown on agar slants for twenty hours, and is then washed off into a small quantity of normal saline solution. It is then tested for purity, placed in sealed tubes, and the bacteria killed by heat at 60° C. for one hour, one-fourth of one per cent. of trikresol being added as a safeguard. The site of inoculation is the arm, at the insertion of the deltoid muscle, the dose to be given subcutaneously. No applicant should be vaccinated who is not perfectly healthy and free from fever at the time. Three doses are given, ten days apart; the first, of 500 million, and the second and third of 1,000 million each. There is usually some headache and malaise, and local reaction consisting of a red and tender area about the size of the palm of the hand, and sometimes tenderness in the axillary glands. During the following forty-eight hours no active exercise is to be permitted. In none of the cases injected have any anaphylactic symptoms been observed. The protection is given at once, and British statistics show that it lasts three years.

Ehrlich's 606 in Syphilis.—H. J. Nichols and J. A. Fordyce report their experience with this new remedy. (See MEDICAL RECORD, October 1, 1910, page 589.)

Creatinin and Creatin Metabolism in Children.—J. P. Sedgwick states that the study of the creatin and creatinin metabolism in children, although a promising one, has been little worked on. The opinion held until five years ago that infants do not excrete creatinin is undoubtedly incorrect. Creatinin is present in the liquor amnii, which may mean that its excretion begins before birth. Creatinin is always in the urine of the first week and in a concentration approximately that of adult urine. Creatin is also excreted during infancy. In later infancy creatinin is present in the urine uniformly, but in much more dilute condition than with adults, or during the first week. Analyses of urine in disease indicate that we may hope to get some clue to the processes of nitrogen metabolism by the study of creatin and creatinin.

Systemic and Oral Conditions.—V. A. Latham attributes the early decay of the teeth in children to the faulty systems of education and bringing up of the present day. The first seven years of life constitute a period of stress and the teeth show the effects as well as the other organs of the body. She gives a rather lengthy list of diseases in which the condition of the jaws and mouth should be thoroughly studied. The stomatologist often has to treat these patients and has opportunities to see them earlier than the general practitioner. Dr. Latham specially mentions Ludwig's angina as a result of dental suppuration, to which adults are sometimes subject as well as children, and which is likely also to be confused with a more recently discovered disorder, viz., Vincent's angina. Stomatitis following as a complication of a number of more or less grave infectious conditions is also mentioned, especially its connection with uremia. The uremic form of stomatitis is usually a serious condition. When the renal conditions are attended to, however, the buccal conditions readily improve. Dr. Latham speaks also of the importance of the polypathogenic part played by the mouth bacteria. The staphylococci and streptococci may start various forms of local or general suppuration from their point of action in the teeth and even general blood poisoning, besides causing the dental anemia or cachexia of Lejars.

The Relation of Blood Platelets to Hemorrhagic Disease.—W. W. Duke reports cases and experiments which he thinks furnish additional evidence that the blood platelets play a part in stopping hemorrhage and that one type of hemorrhagic disease may be attributed to an extreme reduction in the number of platelets. He describes his method of determining the duration of hemorrhage and also the coagulation time of the blood. The bleeding time was determined by making a slight cut in the lobe of the ear and blotting up the oozing blood at half-minute intervals. This gives a series of blots of gradually decreasing size, each representing one-half minute's outflow of blood, and the rate of decrease of the size of the blots shows the rate of decrease of the hemorrhage. The total duration of such a hemorrhage is called the bleeding time, which was found to vary normally from one to three minutes. It was slightly delayed in severe anemia and greatly delayed in cases in which the platelet count was excessively reduced and also in cases in which the fibrinogen content of the blood was excessively reduced and in experimental animals in which both platelets and fibrinogen were reduced. The method is apparently of no value in determining the tendency to bleed in jaundice and hemophilia and in the types of hemorrhagic purpura which have normal platelet count. The method of determining the coagulation time was by comparing hanging drops of the blood to be tested on two slides inverted over a glass of water kept at 40° C. and covered with a warm damp cloth. The normal coagulation time by this method is from five to seven minutes. Wright's method was used in making the platelet count. The normal count, according to Wright and Kinnicut, varies from 200,000 to 350,000. The cases reported belong to the type of hemorrhagic diseases which have a reduced platelet count. Each patient was transfused, causing a marked increase in the platelet count for a few days with a marked relief of hemorrhage. The conclusions as to the facts developed by the study are given as follows: "1. In the cases of hemorrhagic disease summarized, evidently differing in nature and etiology (acute and chronic idiopathic purpura hemorrhagica, chronic ulcerative colitis, aplastic anemia, nephritis), the constant features associated with the tendency to bleed were the reduced number of platelets, and the modification of the clot probably dependent on it, diminished retractility. 2. In the cases reported relief of the tendency to bleed followed not only the rises in the platelet count which occurred with the apparent recovery from the disease, but was associated with the rise brought about by transfusion. In the latter case, the tendency to bleed returned when the platelets disappeared. 3. Experiments in which the platelet count was reduced by benzol failed to show modifications of the coagulability of the blood, which, I think, can account for the hemorrhages of benzol poisoning. 4. The structure and the mode of formation of experimental thrombi make it seem probable, from an anatomic standpoint, that platelets play a rôle in stopping hemorrhage." None of the patients showed such a marked tendency to hemorrhage after transfusion as before, even after the platelet count had dropped to its previous level, and in each of the cases the platelets introduced by transfusion disappeared quickly. The uniform rapidity of rate of disappearance suggests that they are short-lived bodies. Their formation is also rapid. The evidence suggests strongly that platelets disintegrate or are used by the body

in enormous numbers and that their number is kept up by a correspondingly rapid rate of formation.

Operative Treatment of Congential Clubfoot.—C. Ogilvy states that corrective manipulation should begin at birth, and early operation should be done if necessary (seventh or eighth month). Operative procedures will depend on the degree of deformity, and are as follows: 1. Forcible manipulation under an anesthetic. 2. Subcutaneous division of contracted structures. 3. Phelps' open operation. 4. Other bone operations, especially: *a* Excision of a portion of the cuboid in selected cases. *b* Osteotomy of tibia for marked inward rotation. Long-continued and careful postoperative attention is essential. The best results are always obtained when the treatment is begun at birth.

Partial Thyroidectomy in Dementia Precox.—R. Winslow concludes that there seems to be some connection between the thyroid gland and the peculiar affection called catatonia. Partial thyroidectomy in the early stages of this disease exercises a favorable and sometimes a curative effect on the condition. In late stages of catatonia and in the other forms of dementia precox partial ablation of the thyroid is not followed by beneficial results. The operation is attended with the usual dangers of thyroidectomy and should be done with as much care as in exophthalmic goiter, especially in regard to free drainage.

Influence of Colloidal Protection on Milk.—J. Alexander and J. G. M. Bullowa state that increasing the colloidal protection of the casein in cow's milk by the addition of suitable protective colloids tends to improve the digestibility and absorption of both the casein and the fat, and to prevent the formation of indigestible curds and their consequences.

Is Acute Chorea an Infectious Disease?—A. Gordon reaches the conclusion that, similarly to acute poliomyelitis, acute chorea is probably associated with some infectious element. The onset of the disease and its pathologic anatomy render the two affections analogous. The fundamental difference lies in the fact that in one disease the motor cells are being destroyed, hence the paralysis, in the other disease the motor cells undergo irritation, hence the twitching. The destructive effect in the former and the irritating effect in the latter point to a difference in the virus in the two affections. As a final feature of interest in this connection may be mentioned the experiments of P. Guizetti. He injected cultures of staphylococci under the dura mater and in both carotids in dogs and obtained spasmodic movements partly resembling chorea. It is possible that a certain variety of staphylococcus is specific in chorea, but so far it has not yet been determined. Continuous work in this direction may eventually lead to the discovery of the etiological factor and, therefore, of a therapeutic serum.

Unusually Quick Rash Following Injection of Diphtheria Antitoxin.—L. Neuwelt describes a case in which an extensive urticarial rash appeared ten minutes after the injection.

Essential Hemospermia.—A. Nelken describes two cases of this condition, the presence of blood in the seminal discharge, and states that such bleeding is similar to the hemorrhage which occasionally occurs on too suddenly emptying the bladder after prolonged retention.

The Immediate Microscopic Diagnosis of Tumors at the Time of Operation. E. H. Shaw.
Pneumonia: An Inquiry into Some of the Mechanical Conditions Which May Occur in the Chest in Adults Suffering from an Infection with the Pneumococcus of Fraenkel, Etc. W. E. McKechnie.
The Radical Cure of Hemorrhoids: Modified Whitehead's Operation. J. O'Conor.
Malignant Diphtheria with Multiple Lesions in an Infant. J. D. Ralleston.
A Visit to Professor Treufel's Clinic; the Use of "606." J. G. Garson.
The Wandering Womb and Fumigation: A Chapter in Primitive Gynecology. D. McKenzie.

The Etiology and Treatment of Rheumatoid Arthritis.—P. W. Latham puts forward the view that rheumatoid arthritis is due to spinal irritation or congestions or chronic myelitis chiefly affecting the ganglion cells of the anterior horns, but extending also, when the disease is associated with glassy skin, to the ganglion cells in the posterior horns. Regarding the effect of irritative lesions of the pelvic organs, the author refers to Ord's paper suggesting that there is evidence to show that there exists a relation of cause and effect between uterine disorders and arthritis. Ord referred to thirty-three cases of rheumatoid arthritis combined with decided symptoms of uterine disorder or irritation. In a considerable proportion of the cases of arthritic paroxysms coincided with the menstrual periods. In these cases the disorder is regarded as the product of reflex action through the nervous system. According to Latham, the reflex impulses travel along the vasomotor nerves, modify the blood-supply, and so the nutrition of the muscles and tissues to which these vasomotor nerves are distributed. Clinical experience has taught that injuries to the spinal cord, or even to the nerves of a limb, will set up arthritic changes which cannot readily be distinguished from those seen in the earlier stages of rheumatoid arthritis. Concussion of the spine from falling from a height or in skating may also induce arthritic troubles. As regards treatment, in the earlier stages of the malady at all events, it should be directed to the abatement of this spinal irritation, and this can be done most effectively (the exciting cause being removed) by cupping or blistering the spine. The latter is accomplished by means of cantharidal plasters, applied in a definite manner, on each side of the seventh cervical or twelfth dorsal vertebræ, depending upon whether the joints of the upper or lower extremities are most affected. The pain and swelling of the joints are generally much relieved in three or four days after the application of the blisters. As the patient improves, massage, warm baths, and radiant energy are used as auxiliaries in the treatment. Massage must not be employed if it causes pain in the joints.

Clinical Surgery in Japan.—Y. Takaki describes the results of 176 cases of internal piles treated solely by Whitehead's method, stating that this operation properly done is the most radical cure for internal hemorrhoids, and that it is no more serious than other methods. He also reports his results in the treatment of inoperable carcinoma by means of thymus extract, as recommended by Gwyer, stating that this relieves the pain, causes disintegration and reduction in size of the malignant growth, and retards its development.

"Falling of the Womb."—J. B. Hellier describes his operation for the radical cure of severe cases of procidentia, which is a multiple plastic operation, including vaginofixation of the anteverted uterus.

Bilateral Papilledema and Ring Scotoma Due to Sphenoidal Sinusitis.—C. G. R. Wood and G. F. C. Wallis in reporting this case of optic neuritis of nasal origin state that while optic neuritis is not infrequently observed in sinusitis, choked disc, especially of marked degree, is uncommon. The history of sudden blindness with frontal headache in a previously healthy person and the remittent character of the symptoms are very suggestive of accessory sinus affection.

Immediate Microscopic Diagnosis of Tumors.—E. H. Shaw describes his method of receiving a piece of tumor

at the time of operation, and after freezing, cutting, mounting, and staining it, examining it under the microscope, the whole process taking five minutes or less.

Pneumonia: Mechanical and Surgical Conditions, and Treatment.—W. E. McKechnie states that the shortening of the respiratory amplitude is one of the most striking features of pneumonia, and one deserving careful study. As a consequence of diminished amplitude of the respiratory excursions there is a corresponding diminution of the rate of flow of venous blood to the right auricle, for which an increased frequency of respiration will not entirely compensate. The shallow breathing favors an accumulation of carbon dioxide in the blood in two ways: by diminishing the pumping action of the chest the venous blood stream is slowed so that less blood passes through the lungs in a given time, and by preventing sufficient exit of carbon dioxide from the alveolar air. The venous blood then, as a negative colloid, when it becomes more highly charged with carbon dioxide, becomes more and more viscous and flows less readily, thus aggravating the condition of slow circulation arising from the deficient pumping action of the chest, and establishing a vicious circle. These effects can be noted before any extensive consolidation of the lung has taken place, and when occurring thus early seem to be due to the inhibitory nervous reflex initiated at the site of the visceral lesion in the lung, causing defective respiratory action. As the lung becomes consolidated or edematous it loses its powers of expansion and contraction, and thus the mechanical elasticity of its elastic fibers is rendered more or less inoperative. The chief danger in pneumonia of adults caused by Fraenkel's pneumococcus is that the blood may coagulate and form a white thrombus which attaches itself to the tricuspid valve and gradually grows into and blocks up the pulmonary artery. The management of pneumonia reduces itself to: (1) abstaining from any therapy for which there is no clear *rationale*, (2) putting the patient in the best condition, to live long enough to survive the attack, and (3) watching for complications, which are often important and amenable to surgical treatment. It is pitiful to see a patient drugged with poisonous doses of so-called heart stimulants when the circulation is stopping because a clot is blocking up the pulmonary artery. Owing to the fact that intestinal intoxication favors the accumulation of carbon dioxide in the blood, free purging is called for, and during the remainder of the illness no food of any kind should be given. The more empty the abdomen is the more readily can breathing be carried on. Sleep and rest are the chief factors that reduce the production of carbon dioxide to a minimum. It is here that morphine shows itself a most valuable drug. Besides, it counteracts the inhibitory reflex at work in the respiratory center, which shortens the amplitude of respiration. One must always regard pneumonia as a septicemia and be prepared to discover pus, especially in connection with the great serous cavities of the viscera, the pericardium, the pleura, and the peritoneum.

The Radical Cure of Hemorrhoids: Modified Whitehead's Operation.—J. O'Conor describes his method of modifying Whitehead's operation by omitting the forcible dilatation of the sphincter, enabling him to perform the operation in twenty minutes, with comparative ease and little hemorrhage.

A Visit to Professor Treufel's Clinic: The Use of "606."—J. G. Garson states that from the cases shown at the demonstration the new remedy must be regarded as an important and powerful factor in the treatment of syphilis.

The Wandering Womb and Fumigation.—D. McKenzie describes the strange belief of early folk-lore that the uterus is an animal leading a parasitic life within the body of its hostess, which may move about not only inside, but also outside of the latter. Symptoms of hysteria were attributed to this migration. The use of substances of pungent or unpleasant odor was resorted to in order to drive the uterus back to its usual abode. Thus originated the employment of antispasmodics in the treatment of hysteria.

Use and Abuse of Lime Salts in Health and Disease. Sir James Barr.
A Simple Curative Treatment of Cholera. L. Rogers.
Notes on Cholera. M. M. Basil.

Use and Abuse of Lime Salts in Health and Disease.—Sir J. Barr alludes to the researches of Ringer, who showed that for the continuous contractions of the ventricles the presence of minute quantities of a calcium salt are absolutely essential. Calcium increases the efficiency of the beat, but delays dilatation. Ringer also demonstrated in his investigations into the causation of dropsy that even minute traces of the chloride or other soluble salt of calcium greatly and persistently restricted the swelling of laminaria immersed in water. In the treatment of dropsy the chloride of sodium should be excluded, while the calcium salts are beneficial. The presence of calcium is necessary for the clotting of blood and milk. The setting of gelatin is also due to the same cause. The viscosity of the blood is the chief cause of the resistance to the flow in the capillaries, and the principal cause of this viscosity is the lime salts, especially the fixed lime. The latter or that which is linked on to the molecules of albumen increases the viscosity and coagulability of the blood, while the free calcium ions in association with the pituitary and suprarenal secretions increase the tone and contractions of the arteries and arterioles, heighten the blood pressure, and maintain the force and efficiency of the cardiac contractions. In this latter effect the ions of potassium and sodium play an important part. The suprarenal and probably infundibular (pituitary) secretions lead to the retention of lime salts in the blood and tissues, while the thyroid and ovaries increase calcium metabolism, diminish the free and fixed lime in the blood, and thus lessen the viscosity. The calcium salts have been used with great advantage in the treatment of exophthalmic goiter. In capillary hemorrhages whatever treatment the blood pressure may demand, the viscosity of the blood should be increased by the lime salts. In the treatment of thrombosis decalcifying agents are of great value; the lime salts should be eliminated as far as possible from the diet, hence milk, cheese, milk foods, animal jellies, and hard water should be interdicted. The lime salts are very apt to get deposited in any part of the body which is not properly functionating. In arteriosclerosis the lime salts are always deposited in the form of calcium soaps, and afterwards the fatty acid is replaced by phosphoric and carbonic acids. The best way to prevent and improve these degenerative conditions is to maintain a low systolic and a relatively high diastolic pressure. One can stimulate the secretion of the thyroid gland, which increases calcium metabolism and lowers the blood pressure. In this indirect manner the iodine preparations act. Wonderful results are produced by the free and long-continued use of decalcifying agents. Healthy exercise increases calcium metabolism and lowers blood pressure. In the spasmodic or true type of angina pectoris, in which the patient is pale, cold, and haggard, anxious, and suffering severe pain, with great oppression in the chest, there is an excess of lime in the heart muscle, and also, to a less extent, in the blood. In the second type, or false angina, in which the distress and danger are equally great, and in which there are dilatation of the heart, especially of the right

side, and increased intracardiac pressure, there is no increase of lime salts, but rather a deficiency. In Stokes-Adams' disease, for the maintenance of efficient cardiac contraction free calcium ions are essential, hence all agents which increase calcium metabolism do good, such as thyroid gland and iodine. A combination of calcium iodide, potassium chloride, and tincture of iodine is useful, also phosphoric acid with the glycerophosphates of potassium and calcium. In the acute stage of pneumonia the more scanty and the more sticky the expectoration, the more viscous the blood, the more lime salts and leucocytes it contains, *cæteris paribus*, the more favorable the prognosis. In asthma, in whose attacks there is an excess of free calcium ions in the blood, decalcifying agents should be prescribed and a milk diet rigidly excluded. In gout a decalcifying agent like phosphoric acid is useful. In epilepsy all calcium salts do good, but sodium salts, which increase excitability and conductivity of nerve, do harm. The iodide of calcium is efficient in this disease. In locomotor ataxa lime salts are in excess; the treatment that has produced the best results has been phosphoric acid and strychnine, Fraenkel's exercises, and the avoidance of a milk diet. In migraine, as a rule, the lime salts are in excess, and there is intestinal toxemia. In eczema there is a deficiency of lime. Wounds of all kinds heal best when there is a fair amount of lime in the tissues. In congenital hypertrophic stenosis of the pylorus of infancy the causal agent is the excessive amount of lime in cow's milk, setting up first spasm and then hypertrophy of the pyloric walls.

A Simple Curative Treatment of Cholera.—L. Rogers states that the loss of fluid from the blood averages one-third in the mild cases to two-thirds in the most severe and fatal cases. There is also a great loss of the salts, in proportion to the severity of the case. This change accounts for the comparative failure of injections of normal salines in cholera, and furnishes an additional reason for the use of hypertonic solutions in order to replace the chlorides as well as the fluids lost. The result of this treatment during the past two years has reduced the mortality from 59 to 32 per cent. The hypertonic solution approximates in its composition Ringer's fluid, and is injected intravenously. Daily manometer observations have enabled the danger of uremia to be foreseen (patients whose blood pressure remained continuously below 95 mm. dying of uremia), and by using all means to raise the blood pressure to the necessary height the proportion of deaths from uremia has been reduced to one-half. The destruction of toxins in the bowel has been effected by taking advantage of the oxidizing property of potassium permanganate, administered either in solution or in a pill. The mortality, which had been reduced to nearly one-half by the hypertonic saline injections, has now been reduced by the addition of the permanganate treatment to but little more than one-third of the old rate.

Notes on Cholera.—M. M. Basil describes points in this disease that appeared to him new and suggestive during his experience with severe epidemics in Teheran in 1892 and 1903.

Berliner klinische Wochenschrift.

September 19, 1910.

Wassermann Reaction in Wet-Nurse's Milk.—Thomson of Copenhagen has experimented extensively on the subject of the recognition of syphilitic wet-nurses by the presence of the Wassermann reaction in their milk. It might be thought that repeated blood tests would solve this problem, yet the milk test may also have a field as a corroborative resource. When a pregnant woman is expected to serve as a wet-nurse her milk should be examined just before confinement or during the first two days of suckling. A positive blood result gives the usual assurance that the woman has active syphilis. But if no positive result is obtained in this way it is possible that the woman may still have syphilis; and it is just here that a milk test may prove of value. A positive result with milk makes the diagnosis of syphilis highly probable, if this result is attained by using 0.05 c.cm. serum or less. If a positive reaction cannot be obtained by less than 0.1 c.cm. the assurance is not enhanced thereby. In fact, the degree of strength of reaction obtained by fractional amounts was not much in evidence, for in but 6 of 200 cases could it be shown that reaction depended absolutely on the amount of serum used in material presumably non-syphilitic. A positive result in any case with 0.2 c.cm. leaves no doubt as to the presence of syphilis. Negative results in milk tests undoubtedly have a higher value than in blood tests.

Insufflation Narcosis in Man.—Meltzer's method, so-called, is discussed by Unger of Berlin, as follows: Recently Meltzer of New York published his method of insufflation narcosis, which consists esentially in passing a slender tube below the glottis and therewith blowing into the lungs a mixture of compressed air and ether. The animals tested were thus enabled to absorb oxygen without breathing, even when double pneumothorax was present. The author and another were in the act of testing the method on animals when Elsberg was making the first attempt to use the method on man (published in No. 21 of the *Wochenschrift* of this year). The present authors have since tested the method on two human subjects. The results were not all that were expected, but there seems reason to believe that in severe cases of thoracic surgery in which the play of the lung is interfered with there is no mean future for this new resource. In the first case a patient was to be operated upon for a large sarcoma seated in the throat and descending into the thorax. The intervention for its removal was severe, necessitating the opening of the pleura. The patient was first etherized, and as soon as he slept the new method was tested. A flexible stomach sound was passed into the bronchial tube in the head-downward position and an ether flask attached to it. The oxygen was forced into the tube by the oxygen bomb. It is immaterial whether the oxygen passes through the ether or a special tube under a pressure of 12-15 mm. Hg. The operation itself and its immediate consequences were successful, but as the growth was a metastasis from the testicle the ultimate survival is naturally dubious. The results in the second case, however, were somewhat of an offset to those of the first. This case was also one of a tumor of the throat, threatening strangulation; but the mass was tuberculous in character. It was difficult to introduce the tube into the trachea, but the anesthesia afterwards ran smoothly enough. After the operation the patient went through a series of problematic experiences, no less difficult to portray than to explain. The chief symptom was a general subcutaneous edema, which subsided of itself and left the patient eventually in a state of recovery.

Coxa Vara Congenita.—Drehmann describes this condition in abbreviated monographic form; that is, he states apparently all that is to be said of it in two pages, gives ordinary diagrammatic sketches and radiograms, and appends the literature. Naturally, such an article is difficult to condense. The condition, known only for the past five years, is one of the numerous affections which sprang into existence as a result of radiography—that is, without the latter resource it would hardly have been recognized We can only say of it that it is a purely congenital trouble, the nature of which may vary. Naturally, it is not recognized as a rule until some months after birth. The author regards it as essentially a defective development of the femur—the mildest expression of the same,

which in higher degrees may express itself in various clinical forms.

Black Tongue in Nurslings.—Cohn refers to the incidence of this affection in nurslings. The total recorded material of this affection, for all subjects, was collected not long ago by Blegvad, whose article is well known to specialists. The condition is rare in early infancy, and Blegvad, with other case-collectors, mentions but few. In fact, the affection is one usually declared to attack the elderly. Cohn seeks to analyze all cases reported in childhood, without apparently discovering much consensus of data in such material. The author's personal case, while typical, occurred in an infant a little over a year old. About all that can be said of it is that some of the milk teeth became black and carious and broke off.

Münchener medizinische Wochenschrift.

September 20, 1910.

Pachymeningitis Interna Infectiosa Acuta and Meningismus.—Schottmuller discusses the relationship of this actual finding to the meningeal syndrome. The latter is, of course, called into play from various causes. It is a common accompaniment of delirium, coma, mania, sepsis, etc. Contractural or paretic symptoms may coexist, and may radiate over the musculature at large. Common symptoms of meningismus are stiffness of the neck and Kernig's sign. To differentiate between such a palpable condition as acute pachymeningitis and simple meningism may require some positive finding like the results of lumbar puncture. The author's diagnosis in his cited material was confirmed only by autopsy, but something may be inferred from the results of lumbar puncture before death. A most typical syndrome of meningism may be set up by infectious pachymeningitis; and the author seems inclined to associate the two in the clinic. That is, in so-called meningism there may be a slight proliferation of dura cells, resembling mononuclear leucocytes. With this is associated the formation of a false membrane, which stands in some definite relation with streptococci or other germs. In many cases this streptococcic pachymeningitis may be shown to be secondary to a primary focus, such as the endometrium. Lumbar puncture may not expose the actual pathogenic germ in a given case; in fact, the entire pathogenesis of these cases remains obscure.

Surgery of the Bileducts.—Hans Kehr gives a very brief résumé of his twenty years' experience in this field, during which he has operated on over 1,600 cases. It must be recalled that Kehr is only a country surgeon, so that 80 cases per annum of this kind of surgical work constitutes a record in more ways than one. His work is divided as follows: Of 307 conservative procedures of all kinds, including cystotomies and cysticotomies, he lost 2.2 per cent. from operative mortality. Of 384 attempts to extirpate the gall bladder he lost between 3 and 4 per cent., and in 389 choledochotomies and hepaticotomies, his death rate was about the same. Very different were the figures when the gall bladder was removed in connection with disease of the adjoining structures (stomach, intestine, pancreas, and liver itself). But while the mortality in benign affections, so-called, of the nearby organs did not rise much above 14 per cent., the death rate of operations for malignancy in actual or neighboring parts rose to 82 per cent. Thus, in other words, 1,600 miscellaneous operations on the gall-ducts had a total mortality of 16.5 per cent., while if all malignant cases were left out of count this mortality would be about 5.4 per cent. In his endeavor to show that his line of work is necessarily progressive, Kehr states that in his last 72 cases of uncomplicated surgery of the bileducts, etc., but one death took place. His operations are now done under rigid indications.

Dangers of Forcible Dilatation of the Sphincter Ani.—Melchior writes briefly on this subject, reaching the conclusion that forcible stretching of the sphincter in connection with fissure of the anus or otherwise is by no means a procedure devoid of ill results. Permanent incontinence of feces is the chief of the latter. Such a result may, however, be discounted by avoidance of excessive force and by dilation during deep narcosis.

Ascarides Intoxication.—It has been known for many years that round worms are in some manner able to poison individuals even by external contact, but the nature of this poisoning is a mystery. The parasites are known to contain an aromatic, pepper-like substance which may be extracted by alcohol. The author, Goldschmidt, was himself a sufferer from ascaridiasis of outward origin for nine years, and has had a number of cases under treatment. He finds that some people are immune to this affection, and that the extract of the worms does not always cause symptoms. On the other hand, there is such supersensitiveness in others that even handling the parasites causes ascaridiasis. The latter term has no necessary connection with parasitism; it does not appear that the author ever suffered from round worms as an intestinal parasite. But not a few zoologists have developed the affection from studies pursued on the worms. A peculiar conjunctivitis and lachrymation is one of the chief symptoms. The wives of two experimenters were always able to tell when their husbands had been at work on ascarides. In certain cases, including the author's, sneezing was the principal symptom. Cough, asthma, and a whole train of symptoms of irritability of the upper air passages were quite constant. Nausea and vomiting have also been noted. The entire range of symptoms points to exposure to a pungent, irritating substance. Of great clinical importance is the relation between external ascaris poisoning and that which is due to intestinal parasitism. In the latter affection the intestinal mucosa and nervous system appear to suffer chiefly. In extreme cases of round-worm parasitism the toxic principle may possess the power to kill without causing structural lesions.

Report of the Finding of the Bacillus of Hansen in the Menstrual Blood of a Leprous Woman.—A. Serra says that the bacillus of leprosy causes alterations in the genital organs both of males and females. In Sardinia he found the germ of leprosy in the genitals of 16 lepers examined, and menstrual disorders in 7 out of 20 females. He made a systematic examination of the menstrual blood and found negative results in several cases. But in one woman with a mixed leprosy and a marked pemphygoid eruption he found the bacillus of Hansen in the blood globules of the menstrual flow taken directly from the uterus.—*La Riforma Medica.*

Mental Troubles in Chorea.—André Pelissier believes chorea to be a toxi-infectious condition which acts on the brain as well as the motor system. When we see it following measles, scarlet fever, typhoid, and other infectious diseases it is difficult to avoid this conclusion. The author gives us an illustrative case in which the young patient having a syphilitic heredity, with tuberculosis and psychoses in her ancestry, was attacked by chorea. This later changed to mental confusion, followed by catatonia, and again the choreic movements occurred. The form of these mental states after chorea is protean. Hallucinations, confusional states, catatonia, and melancholy are all seen. In the case of this patient there was an hereditary predisposition to disease, and the acute infective process was easily engrafted on the unstable mental condition. Catatonia is a syndrome that follows epilepsy, hysterical convulsions, chorea, manic-depressive insanity, and dementia præcox. Chorea, mental confusion, catatonia, and chorea repeated were all manifestations of a single infectious cause.—*Le Progrès Médical.*

Book Reviews.

Manual of Tropical Medicine. By Aldo Castellani, M.D. (Florence); Privat-Docent (Naples); Director of the Clinic for Tropical Diseases, Ceylon; Physician, Seamen's Ward, General Hospital, Colombo; Professor of Tropical Medicine and Lecturer on Dermatology, Ceylon Medical College; Member of the Royal Society's Commission on Sleeping Sickness in Uganda, 1902-1903. And Albert J. Chalmers, M.D. (Vict. and Liv.); F.R.C.S. (Eng.); D.P.H. (Cam.); Registrar and Lecturer on Pathology and Animal Parasitology, Ceylon Medical College; Pathologist, the General Hospital, Colombo; Holt Fellow, University College, Liverpool, 1890; Medical Officer, Gold Coast Colony, 1897-1901. New York: William Wood & Company, 1910.

This is the most recent addition to the rapidly growing literature of tropical medicine. It is based on what the authors found it necessary to acquire and to use during their work in the tropics. In order to keep the book as small as possible, all reference to practical laboratory methods is omitted, as the practitioner working in the tropics is supposed to possess works which contain such details. In spite of this, the book is of a goodly size, and is unusually complete. The first part has chapters on the history of tropical medicine, tropical climatology, effect of tropical climate on man, and incidence of disease in the tropics. The second part is on the causation of disease in the tropics, and treats of the physical, the chemical, and the biological causes of disease; the last of these takes up by far the largest space, as it is by far the most important. The whole of this part is extremely well done, and the sections on the protozoa will form a useful adjunct to any modern work on practice. The third part is entitled "The Diseases of the Tropics," and consists of three sections, dealing respectively with fevers, general diseases, and systemic diseases. The authors have devoted particular attention to the descriptions of treatment, going into details which their experience in the tropics has shown them to be necessary. The book is the most complete that has yet appeared on tropical diseases; it is appropriately dedicated to Sir Patrick Manson, "The founder of scientific tropical medicine"; and the work is eminently satisfactory, whether viewed as a scientific study or as a practical guide for the physician in the tropics.

The Evolution of Man. A Popular Scientific Study. By Ernst Haeckel. Vol. 1. Embryology or Ontogeny. Vol. 2. The Evolution of the Species or Phylogeny. Translated from the Fifth (enlarged) Edition by Joseph McCabe. New York: G. P. Putnam's Sons, 1910.

The English-speaking scientist is to be congratulated at having now within his reach the latest edition of this classical work on embryology and evolution. One need not go the whole way with the author to welcome his work, and, indeed, the work itself is less radical than the comments on it, by friends and foes alike, would lead one who knows not Haeckel to suppose. The present edition is conveniently divided into two volumes; the first on the development of the individual, the second on that of the race; the first volume being prefaced with an historical account of the development of the science of embryology, in which, of course, Haeckel, as is his wont, continually recurs to his doctrine of the law of recapitulation, that ontogeny is a recapitulation of phylogeny, or in other words, that in the various stages of development of the embryo one may study the progress of evolution from the single cell to man. The illustrations are striking, not only in their number, but in their excellence, and they serve to render more easy of comprehension a most abstruse, albeit fascinating subject which remains difficult despite the beautifully clear description of the author and the idiomatic English of the translator.

The Diseases of Infancy and Childhood. Designed for the Use of Students and Practitioners of Medicine. By Henry Koplik, M.D., Attending Physician to the Mount Sinai Hospital; Consulting Physician to the Hospital for Deformities, formerly Attending Physician to the Good Samaritan Dispensary, the St. John's Guild Hospitals, New York; ex-President of the American Pediatric Society; Member of the Association of American Physicians, and of the New York Academy of Medicine. Third Edition, Revised and Enlarged. Illustrated with 204 Engravings and 30 Plates in color and monochrome. Lea & Febiger: New York and Philadelphia, 1910.

The third edition of this favorite work on pediatrics shows the marks of a conscientious and judicious reviewer. Among the subjects more or less extensively reviewed are infant feeding, the central palsies, infantile paralysis, tetanus, pyelitis, and gastric disorders. Among the subjects treated of for the first time are dwarfism and idiocy in general; the latter condition is treated of in at least three different places, and not very fully anywhere. This section, or these parts of sections, might serve as a text to some Roosevelt of medical literature to declaim against the practice of making a show at completeness by adding to the number of titles without putting anything of value under the titles. Apart from this superficial glance at infantile psychiatry, the book is everything that could be desired by the student of pediatrics, for the descriptions are most satisfying in their completeness without tiring by their length, and they are clear. The illustrations are also to be commended.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. de Schweinitz, A. M., M. D., Professor of Ophthalmology in the University of Pennsylvania and Ophthalmic Surgeon to the University Hospital; Consulting Ophthalmic Surgeon to the Philadelphia Polyclinic; Ophthalmic Surgeon to the Philadelphia Hospital; Ophthalmologist to the Orthopedic Hospital and Infirmary for Nervous Diseases. With 351 illustrations and 7 chromolithographic plates. Sixth edition. Thoroughly revised. Philadelphia and London: W. B. Saunders Company, 1910.

The first edition of this standard work appeared eighteen years ago, and the fact of its continued existence and growth affords ample proof of its accuracy and the practical value of its teachings. For the present edition parts of several important chapters have been rewritten, and a number of subjects have been introduced and are treated of here for the first time. Among the latter are the use of the astigmatic lens, obstetric injuries of the cornea, posterior scleritis, cyanosis of the retina, atoxyl amblyopia, ocular complication of accessory sinus disease, intermittent exophthalmos, Herbert's operation, Smith's cataract operation, Lagrange's operation, and a number of others. There are not many general works on the eye that are more satisfactory, taken all in all, than this tried and proved treatise of de Schweinitz.

Lehrbuch der Ohrenheilkunde. Von Dr. Victor Urbantschitsch, O.O. Professor der Ohrenheilkunde an der Wiener Universität und Vorstand der K.K. Universitätsklinik für Ohrenkranke. Fünfte, vollständig neuarbeitete Auflage. Mit 156 Abbildungen im Texte. Berlin, Wien: Urban & Schwarzenberg, 1910.

It would appear superfluous to allude to the merits of this work, the eminence of whose author has for a long time placed it among the standard books in its field. This edition represents a complete revision and enlargement of the last edition. The references to the literature are particularly voluminous, the text covers fully every phase of otology, including the education of deaf-mutes, the forensic aspects of diseases of the ear, their relation to life-insurance, and to service in the army, and the index is complete. The work includes all the recent contributions to this important specialty.

Genesis. A Manual of for the Instruction of Children in Matters Sexual. For the use of Parents, Teachers Physicians and Ministers. By B. S. Talmey, M.D., Former Pathologist to the Mothers' and Babies' Hospital, and Gynecologist to the Yorkville Hospital, New York. With nineteen cuts, forty-seven drawings in the text. New York: The Practitioners' Publishing Co.

This is the most recent volume on sexual matters. It consists of two parts: the first, containing nine chapters, is devoted to the task of proving the necessity of instructing the young in sex matters. "It is naturally more or less of a repetition of what all the other authors have said on the subject." The second part is headed "Special Lessons"; the first, is for infancy and early childhood; the second, for children from 4 to 7 years of age; the third, for children from 7 to 10; the fourth, for children from 10 to 13; the fifth, for children from 13 to 16; and the sixth, for children from 16 to 18 years of age. Thus the children are all provided for. As a sample of the first part, or General Lessons, we quote from the chapter on Moral Confusion:—"The girl who blushes the most readily and hangs her head in shame at the slightest indiscreet word usually offers the least resistance when one gets her behind the door." In the lesson for infancy we find:—"Just as the eyes are sensitive and the sight easily damaged, so the organs of sex are sensitive and if not let alone, great harm may result. For that reason they must only be touched with a pair of tongs." Even infants, if they can understand anything at all about the matter, might wonder why either their eyes or their organs of sex are to be touched with a pair of tongs.

Society Reports

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-fourth Annual Meeting, Held at the Arlington Hotel, Washington, D. C., May 3, 4, and 5, 1910.

THE PRESIDENT, DR. WILLIAM ALLEN PUSEY OF CHICAGO, IN THE CHAIR.

President's Address—The Therapeutic Use of Refrigeration, Particularly with Solid Carbon Dioxide.—Dr. PUSEY stated that the principle underlying the therapeutic use of solid carbon dioxide, as of liquid air, was the production of a relatively deep, sharply defined inflammatory reaction in living tissue by sudden intense freezing. The advantage of the method was that the reaction could be regulated so that one could accurately produce all degrees of effect upon tissues, from an evanescent inflammatory reaction to a reaction so intense that it resulted in complete destruction of the involved tissues. The therapeutic indications for the use of refrigeration were found in the following conditions: First, those in which the production of a stimulating reaction was beneficial. Here only conditions covering relatively small areas would come into consideration because of the impracticability of using the applications over very large surfaces. Second, those in which it was desired to destroy certain tissues in the skin by the production of an interstitial sclerosis. Third, those in which it was desired to produce immediate destruction of masses of diseased tissue in the skin.

Dr. Pusey said that as a stimulant of chronic inflammatory lesions, solid carbon dioxide offered prospects of some usefulness in circumscribed limited patches of chronic eczema, lichen planus and similar inflammatory dermatoses. Lupus erythematosus was one of the diseases in which liquid air had been used with great benefit before the introduction of solid carbon dioxide, and most of those who had used solid carbon dioxide in this affection were strongly impressed with the value of the method. In the early work of White and others with liquid air, efforts were made to treat boils and carbuncles and other infections, and solid carbon dioxide had been suggested in chancroids, condylomata, lupus vulgaris, and other infectious lesions of the skin. There seemed to be nothing of value above other well-known agents to be expected from the use of carbon dioxide in acute infections of the skin, like chancroids and condylomata, and the speaker said he did not believe it was an addition of any importance in such diseases. Zeisler, Sutton, and Jackson and Hubbard had reported good results from short, superficial freezing in chloasma. Good results had also been reported in the removal of tattoo marks and powder stains; others had found the method a failure. Improvement or removal of keloids or hypertrophic scars had been reported by Hoffman, Schaleck, and others. Sutton in a personal communication reported excellent results in a case of xanthoma planum The method had also been recommended for the removal of warts. Nearly all of the workers who had used carbon dioxide in nevus reported favorably upon it in comparison with all other methods of treating these lesions, and the method furnished an almost painless and a convenient means of removing moles.

Extramammary Paget's Disease, with Report of a Case Occurring on the Forearm, Associated with a Nevo-Carcinoma.—Dr. M. B. HARTZELL of Philadelphia read this paper, which he illustrated with microphotographs and which included the report of a case with its clinical and histological features. He compared this with other cases which resembled it more or less and discussed the relationship of the dermatitis to Paget's disease and carcinoma. He said it seemed to him that the cases which he had ventured to call extramammary Paget's disease afforded special opportunity for determining the real nature of this extremely interesting malady—for deciding whether the disease was one *sui generis*, as maintained by Unna and others, or whether it was carcinoma from the beginning, as was asserted by a number of recent writers. The careful study of these cases ought also to enable us to determine whether the cutaneous disease was a primary one, followed only after a considerable interval by carcinoma, as had long been believed, or whether, as Jacobaeus, Hirschel, and others asserted, the skin symptoms were only a secondary manifestation of a deeper lying carcinoma which had already existed for some time. The correct decision of this question was of the utmost practical importance, for upon it depended the plan of treatment to be adopted. If the former view was the correct one, then there was a reasonable prospect that early and prolonged treatment by the *x*-ray or by radium might effect a radical cure; but if the latter, then every day's delay in thoroughly removing by surgical measures the entire disease was valuable time lost and impaired by so much the patient's chances of recovery.

Dr. SAMUEL SHERWELL of Brooklyn said he was present when Paget first demonstrated this disease at the International Congress of Dermatology in London, in 1881, and the following year he himself had a case which was typical in character and which he reported to the New York Dermatological Society. The speaker said he had always looked upon these lesions as carcinomatous from the beginning.

Dr. A. RAVOGLI of Cincinnati said he was decidedly of the opinion of Dr. Sherwell that these lesions were carcinomatous from the beginning and that the initial onset was a pre-cancerous condition.

Dr. J. A. FORDYCE of New York showed a photograph of a case of Paget's disease of the nipple with secondary lymphangitis and areas of ulceration close to the original patch. The latter was probably the result of the breaking down of the cancerous lymphangitis. He believed that cases of extramammary Paget's disease, at least those which clinically resembled Paget's disease of the nipple, were more common than was usually supposed.

Dr. J. NEVINS HYDE of Chicago said that many surgeons held the view that in every case of Paget's disease of the nipple the mammary gland was already involved, and they looked askance at any method of treatment short of complete ablation of the breast. If the cases so well collated by Dr. Hartzell showed that we might have a primary dermatitis of a carcinomatous character, developing later into Paget's disease, we certainly were in possession of a fact of value from a therapeutic point of view.

Syringocystoma.—Dr. OLIVER S. ORMSBY of Chicago read this paper, in which he recorded the findings revealed in the study of a case in which the clinical diagnosis of syringocystoma was made. He said that in the mass of literature on this subject there appeared to be pretty distinct groups of cases which presented a sufficient number of common details, both clinical and pathological, to explain why all had been classed together by most writers. In group one, to which the cases of multiple benign epitheliomata belonged, the disease appeared to be hereditary. The lesions began early in life, and often several members of one family were affected. Here the lesions predominated on the face and head and were variously described as nodules of different sizes, whitish, yellowish-red, translucent, etc., in some instances going on to softening and to evolution—true epitheliomata. Brooke, Fordyce, Hartzell, and others had traced the origin of these epithelial growths to the rete and the sheaths of the

hair follicles. To identify the second group, various terms had been used, according to the conception of the writer as to the point of origin of the affection. Among these terms were eruptive hydradenoma, adenoid epithelioma of the sweat glands, syringocystoma, lymphangioma, etc. In the majority of these cases the lesions occurred most often on the trunk. Heredity played no part in this affection. The lesions varied in color, size, and shape, but they were nodules and perhaps much softer in consistency than those described in the first group. In the latter the sweat glands, ducts, the lymph and blood vessels had been thought to be the points of origin of the growths. Dr. Ormsby then gave in detail the history of a case in which the clinical diagnosis of syringocystoma was based upon a due consideration of all the points, both clinical and histological. Clinically it was more extensive than other recorded cases, and spontaneous disappearance of lesions occurred which had not been recorded previously. It was entirely unlike any case of multiple benign cystic epithelioma. Histologically the sections showed the most marked pathological process at all times in the region of the sweat ducts. Some sections apparently demonstrated the fact that the cells were the proliferation product of the cells of these ducts. A connection between the hair follicle or the epidermis and the cell masses could not be demonstrated. Whether the sweat glands themselves added to the growth was not proven, although it seemed probable. Finally, from the fact that the lesions developed over so great an area, practically symmetrical, and showed such marked effects on the involvement of the sweat apparatus, the problem of local irritation from some error of metabolism or otherwise must be ruled out, but so far that work in this respect had been neglected.

Dr. S. Pollitzer of New York referred to the case reported by Török under the name of syringocystadenoma and that reported by Kaposi under the name of lymphangioma tuberosum multiplex, which contrasted enormously with the case described in Dr. Ormsby's paper, or with the case of Perry, which was published under the name of adenoma of the sweat glands. The speaker said he could not convince himself that all these cases belonged to the same category.

Dr. M. B. Hartzell of Philadelphia said there was no longer any doubt that a large proportion of these cases, which had been reported under various names, were examples of epithelial neoplasms having their origin in the basal layer of the epidermis or the columnar cells of the hair follicles.

Dr. Martin F. Engman of St. Louis said that the question of cell growth was a subject that had received comparatively little attention in connection with diseases of the skin, but in other fields of science and medicine many significant facts had been brought forward.

Dr. Ormsby then closed the discussion.

Further Observations on the Technique of an Efficient Procedure for the Removal and Cure of Superficial Malignant Growths.—By Dr. Samuel Sherwell of Brooklyn. His method of dealing with superficial malignant growths consisted, first, in curettage, which should be thorough, deep, and efficient. Immediately following this there should be an equally thorough application of an escharotic, preferably, in the writer's opinion, a 60 per cent. solution of the acid nitrate of mercury, which should be allowed to remain, with various reapplications at the time of operation, for varying lengths of time, according to the delicacy or density of the tissues involved. About from five to twenty minutes would be about the limits. The final step in the operation was the, at least, superficial neutralization of the caustic agent by some alkaline medium, and of these sodium bicarbonate seemed to be the best. A few grains of this, powdered on and pressed into the wound, immediately formed a plain scab or crust which should be allowed to remain *in situ*, untouched and dry, until it fell or rather was pushed off by and with the process of healthy repair beneath, leaving a healthy scar, and usually a relatively insignificant or not very noticeable one. Dr. Sherwell said his experience with this method, which had never changed, had been coincident and identical, or almost so, with that of his dermatological life and practice, a period of nearly forty years. During that time he had operated on many hundreds of these cases of malignant growths in this manner. Recurrences or relapses had been comparatively few; he could not give the exact figures, but it was probably less than 10 per cent., and usually a second operation would diminish even that. The author claimed for his special technique rapidity of results, decided freedom from recurrences, relative absence of cosmetic deformity, and, when the procedure was thoroughly carried out, little or no pain, either during or after the operation, and no necessity for repeated dressings when the indications were properly cared for. In connection with his paper, Dr. Sherwell exhibited a number of photographs showing the lesions before and after treatment.

Dr. J. A. Fordyce of New York said he could personally testify to the efficiency of the acid nitrate of mercury, as advised by Dr. Sherwell, in the treatment of superficial epitheliomata. The speaker said he had used it in a number of cases with excellent results.

Dr. Henry W. Stelwagon of Philadelphia said that for the past four or five years he had preferably treated superficial epitheliomata by thorough curettage, followed by the application of some caustic, and among the latter he thought the acid nitrate of mercury solution was one of the best, as the wound, if small, required no subsequent dressing; a crust was formed under which healing went on, leaving a practically healthy scar at the end of three or four weeks.

Dr. Edward B. Bronson of New York said it was especially in cases where the orbit was involved that the most remarkable results had been obtained by Dr. Sherwell.

Dr. Sherwell, in closing, said he had resorted to this method for thirty-five years and his faith in the remedy had become stronger as time went on. Curiously enough, the most unfavorable cases, in his experience, had been those in which the lesion was situated about the center of the cheek; whether that was due to the peculiar circulation of these parts, or to the adhesions of the skin to the deeper tissues, he did not know; in fact, it was difficult to frame a reason.

Cancer in Tar Workers.—Dr. Jay Frank Schamberg of Philadelphia in this paper stated that cancer of the skin exhibiting special characteristics had been encountered in chimney-sweeps and in tar and paraffin workers. He reported in detail a case of multiple cancer of the skin in a tar worker who developed several scores of epitheliomatous lesions in various stages of development upon the hands and forearms, and a large epithelioma upon the scrotum. That something resident in coal tar, crude paraffin, and soot was capable, after the lapse of years, of stimulating the growth of epithelial cells and of leading to cancer in certain subjects seemed indisputable. Ludwig and others had suspected carbolic acid which he likewise found in tobacco residue, but there did not seem to be much support for such an assumption. Inasmuch as radium had proven to be capable of stimulating epithelial proliferation and cancer could be produced by the *x*-rays, the thought occurred to Dr. Schamberg to determine whether coal tar emitted any rays. To test this he placed a copper cent, a flat key, and a small brass numeral upon a photographic plate in a pasteboard negative box lined with black paper. Upon the under surface of the lid he attached a piece of cardboard smeared with coal tar so that the tar faced downward. This box

was inclosed in a black japanned tin cash box and the latter was shut in a dark closet for twenty-four hours. When the plate was developed a distinct shadowgraph of the three objects was seen upon the negative. This work was done so recently that there had not been time to carry out further investigations. If coal tar was proven to be radioactive it would seem that this radioactivity might be responsible for the cancer in tar workers. Volkmann and other writers long ago noted that uncleanliness, *i. e.* negligence in removing tar or paraffin from the skin, was a factor in the production of the cancer. Tar might be lodged in the orifices of the skin or in the furrows of the scrotum and exert for years an influence upon the adjacent epithelial cells. Furthermore, only certain kinds of coal seemed to be provocation of the cutaneous changes. In Germany the so-called brown or cannel coal from which paraffin was made was responsible. Chimney-sweep cancer appeared to result almost exclusively from the burning of "pit coal" used for fuel in England. It was possible that certain coal might contain radioactive substances and that in other coal such substances might be absent.

Dr. Samuel Sherwell of Brooklyn said that while he had long ago accepted the theory that more or less continuous irritation was an important etiological factor in the production of cancer, it was rather remarkable that the cancer so often occurred in parts that were not exposed to any such irritation. Cancer of the nose, for example, almost always occurred above or below the point where the eye-glasses were fixed.

Dr. Martin F. Engman of St. Louis said the question of cancer in relation to radioactivity was particularly interesting to dermatologists on account of the fact that cancer occurred on the exposed portions of the body more frequently than elsewhere.

Dr. A. Ravogli of Cincinnati said he had seen cases where acnelike pustules were produced from the application of tar, and it was possible, he thought, that the epitheliomata described by Dr. Schamberg might develop on the basis of acne pustules observed in tar eruptions.

Dr. William A. Pusey of Chicago said that even if it were positively demonstrated that tar had a moderate degree of radioactivity, he would not be inclined to attach much importance to it in this connection. Radioactivity was simply one form of irritation that stimulated the processes that culminated in epithelioma. In estimating the factors that contributed to the production of epithelioma there was no reason to attach more importance to radioactivity than to other forms of irritation.

Dr. Schamberg then closed the discussion.

Nodular Tuberculosis of the Hypoderm.—By Dr Grover W. Wende of Buffalo. This was the clinical report of a case in which deep-seated nodules constituted the only type of lesion. They were limited to the face and disappeared without apparent alteration of the skin, but produced upon disappearance anchylosis of the temporomaxillary articulation and deafness of the right ear. The duration of the eruption was six years. By microscopic study, tuberculin tests, and guinea-pig inoculations the case was proven to be one of nodular tuberculosis of the hypoderm. It was a form of tuberculosis of the skin which showed no analogy with the generally recognized forms of cutaneous tuberculosis due to the invasion of the integument by the tubercle bacilli, like that of lupus vulgaris, tuberculosis verrucosa, tuberculosis disseminata, and tuberculosis ulcerosa.

Dr. Howard Fox of New York mentioned a similar case that he had shown at a recent meeting of the New York Dermatological Society in which a probable diagnosis of Darier's type of sarcoid was made.

Dr. A. Ravogli of Cincinnati said he would not be surprised to learn that the case reported by Dr. Wende began in the form of an erythema induratum from the skin, or from a tubercular ulcer from the mucous membrane of the mouth, from which the tubercular process found its way to the joint.

Dr. J. A. Fordyce of New York said the case so well reported by Dr. Wende was an illustration of the value of careful clinical observation combined with histological investigation. With the aid of the latter we were broadening our clinical ideas in regard to tuberculosis of the skin.

Dr. William T. Corlett of Cleveland said that observation taught us that many clinical forms of superficial tuberculosis of the skin existed.

Dr. Wende in closing said he believed that in the case he had reported the disease primarily occurred locally in the skin. The case illustrated the importance of biopsy for microscopical examination, as there was no suspicion of the real condition before it was made.

Report of a Case of Sporotrichosis in Man.—Dr. James Nevins Hyde and Dr. D. J. Davis of Chicago presented a paper on sporotrichosis occurring in a patient who lived in North Dakota and who had been in contact with horses that were supposed to have suffered from glanders. It was discovered that these horses were probably the victims of mycotic lymphangitis (pseudofarcy), and the authors reported that the Bureau of Animal Industry in Washington recognized the identity between the organism obtained from animals in North Dakota similarly affected and those presenting similar symptoms two years ago which had been studied in Butler, Pa. Further, the Pennsylvania organism had been recognized as identical with the Chicago organism by Drs. Frothingham and Page of Harvard University, and, finally, the two authors recognized the identity between the organism obtained from the human patient in North Dakota and specimens of the Butler organism sent to Chicago. The paper concluded with a demonstration of the essential differences between the sporotrichum Schenckii and the saccharomyces farciminosus of Tokishige.

Mycosis Fungoides, with Report of a Case.—By Dr. Lucius C. Pardee and Dr. Robert F. Zeit of Chicago. In summing up the various features presented in this report, the authors said there could scarcely be any doubt that the case was clinically one of mycosis fungoides. All the classical features of this disease, as described by numerous observers, were present. The premycotic or prefungoid stage was marked and extended over a known period of at least two years. The lesions at that time were typical of the well-known erythematous form and were accompanied by the usual intense pruritus. These were followed in the course of time by the formation of fungoid tumor masses on various portions of the body which microscopically had the aspect ordinarily described as that of small round-celled sarcomata and which underwent the usual course of development, with occasional retrogressions. The blood findings were those of progressive anemia until toward the end of life, when the characteristics of a lymphatic leukemia were rapidly added and dissolution followed. The autopsy developed the findings of lymphatic leukemia plus the gross aspect of mycosis fungoides.

Dr. William T. Corlett of Cleveland mentioned a similar case that was at present under his observation.

Dr. Samuel Sherwell of Brooklyn said he had observed in a number of cases of sarcomatosis and mycosis fungoides that arsenic exerted a markedly beneficial influence on the disease, although other men, apparently, had not been so fortunate.

Dr. J. A. Fordyce of New York said that from most of the text-books it was difficult to get any conception of where mycosis fungoides belonged, whether to the infectious granuloma or to the sarcomatous or leukemic

group of skin diseases. The paper of Drs. Pardee and Zeit showed that it belonged to the latter.

Dr. WILLIAM S. GOTTHEIL of New York said that in a case of mycosis fungoides seen at the Lebanon Hospital the autopsy showed all the organs studded with nodules, which were apparently purely sarcomatous.

Dr. LOUIS A. DUHRING of Philadelphia said the case under discussion illustrated the possible relation of skin lesions to general medicine. The lymphatic manifestations, which were often absent in the typical commoner cases of mycosis fungoides, were very prominent in this case, which rendered it of much interest to the general practitioner and pathologist as well as to the dermatologist. As to the value of arsenic in this affection, the speaker's experience was similar to that of Dr. Sherwell. Under the caption of mycosis fungoides we had several forms of disease which could not well be classified under the same head and which showed that so-called mycosis fungoides was not in all cases precisely the same disease pathologically.

Fibroma Molluscum, or Universal Neurofibromatosis.—Dr. A. RAVOGLI of Cincinnati detailed a case of this kind which was reported on account of its relative rarety. The affection seemed to be a congenital one. The mollusca ranged in size from that of a pinhead to a hazel nut and were scattered over the entire body. The lesions showed no relation to the lines of the skin, nor to the underlying nervous ramifications. The tumors had their origin in a deep subcutaneous nodule. After reaching their full development they underwent degeneration, gradually disappearing and leaving a pigmented spot. It was apparently a disease of the nervous system involving the terminal filaments of the cutaneous nerves.

Dr. WILLIAM S. GOTTHEIL of New York said that while neurofibromatosis was a well-sounding name, the question was whether it was appropriate. In the cases that he had seen and examined in the small tumors they found something which they could not demonstrate as anything but pure fibroma, without any connection with the nerve sheaths. In the larger growths there was myxedematous degeneration. In none of his cases did they find any distinct connection with the sheaths of the nerves and there were no nerve fibers in the tumors.

Dr. LOUIS A. DUHRING of Philadelphia said that in this disease, as in mycosis fungoides, we had several varieties and aberrant types. In the so-called Recklinghausen's disease the pigmentation was marked, and it was in this degree of pigmentation that they chiefly differed from the other types so familiar to observers. The majority of these cases might be classed under the head of simple fibroma molluscum and thus differentiated from neurofibromatosis. In the average case of the former there were no subjective symptoms and in the course of the disease there might in time be retrogressions or other changes.

Dr. RAVOGLI in closing said that most of the writers on this subject did not make much distinction between fibroma molluscum and neurofibromatosis. In his own case the lesions had their origin from a deep, subcutaneous nodule, developing into peculiar growths which were composed of connective tissue fibers, and for that reason he called them fibromata. He had made careful and repeated search for the nerve fibers without finding them.

Exposure to the Sun as an Etiological Factor in Alopecia.—Dr. GEORGE F. HARDING of Boston said that his deductions from the observation of 312 cases of alopecia in young people between the ages of twelve and twenty years would indicate that exposure to the sun was harmful rather than beneficial to the hair and scalp. These patients were seen in private practice during the past four years, and all of them had been for a year or more going in the open without head covering. The exposure in the majority of the cases occurred in the summer. Over 200 spent their summers at the seashore and in these the symptoms were the most pronounced. A large proportion (293) were blondes; this might have been merely a coincidence. On the other hand, it might be accounted for under the old theory that persons and animals with dark hair and skin were less sensitive to the sun's rays than blondes. The fact that light hair was, as a rule, much finer and delicate than dark might also be taken into consideration. The symptoms in these cases were quite constant, but varied in degree with the amount of exposure which had been undergone and somewhat with the individual. The hair was dry, lusterless, and faded; there was an evident lack of sebaceous secretion, with itching. The alopecia, as a rule, showed itself in those cases of but one season's exposure about a month or six weeks after the return to the city and responded quite readily to treatment. In those who had had several seasons of exposure without intervening treatment the fall had been continuous and baldness was often marked. Those cases did not respond well to treatment and the prognosis was decidedly unfavorable for a good growth of hair.

Dr. H. W. STELWAGON of Philadelphia said he thought that moderate exposure both to the sun and air were really of great advantage to the scalp and hair. Slight exposures to the *x*-rays would occasionally start a regrowth of hair. There was no doubt that the nervous system was a factor in the loss of hair.

Dr. ANDREW P. BIDDLE of Detroit said that for many years one of his confrères had proven to his own satisfaction that loss of hair was due to a poison produced by improper breathing.

Vaccine Therapy as Applied to Cutaneous Diseases.—Dr. T. CASPAR GILCHRIST of Baltimore opened the discussion with a paper on this subject in which he confined himself to the results of his own experience with the use of vaccines in the treatment of cutaneous diseases at the Johns Hopkins Dispensary and in private practice during the last three and one-half years. Over 300 cases had been treated. As far as vaccine therapy was concerned in the treatment of cutaneous affections, Dr. Gilchrist said his experience might be summarized as follows: He had found it to be a distinctly valuable adjunct to our therapeutics. The staphylococcus albus vaccine was of undoubted value in the treatment of all pustular affections of the skin, but especially, in his experience, in the treatment of relapsing furunculosis, staphylococcic dermatitis, sycosis-non-parasitica, in certain forms of eczema, in pustular rosacea, and in acne when the disease was largely secondarily infected with the staphylococcus albus. He had also found the vaccines to be of value in the treatment of erythema multiforme, especially of the relapsing bullous type, and in rosacea where the flushings were decreased by the vaccine therapy. It was also helpful in dermatitis herpetiformis and pityriasis rosea, so much so that he would recommend vaccine therapy to be tried when the disease did not yield to the usual method of treatment. *Bacillus acne* vaccine he had found to be of great value, especially in the treatment of those chronic nodular relapsing types of acne vulgaris, and it had proved to be in his hands in a great many cases a curative agent.

Bacteriotherapy in Certain Diseases of the Skin.—Dr. MARTIN F. ENGMAN of St. Louis discussed this phase of the subject and presented the following conclusions: 1. The dose of all forms of vaccines should be at first small. Doses of bacterial suspensions were, of course, approximate. 2. Small continuous doses were best. 3. Increasing the dose was frequently risky. 4. Stock suspensions they had found very reliable and could be used in most instances. 5. Autogenous vaccines were indicated when stock suspensions failed. 6. Clinical indications

alone had guided them in their latest and best results. 7. The opsonic index had proved to be unreliable and impracticable and was not necessary. 8. The failure to obtain results in vaccine therapy might be due to faulty technique. 9. Vaccine therapy would fail in a certain percentage of cases. 10. Vaccine therapy was indicated in diseases of the skin due to a specific microorganism. 11. In vaccine therapy we had at last a reliable beneficial agent in combating the deeper and more virulent staphylococcic infections of the skin.

Vaccine Therapy in the Treatment of Diseases of the Skin at the Massachusetts General Hospital.—By Drs. Harvey P. Towle and George P. Lingenfelter of Boston. The authors stated that before any new method in medicine or surgery could attain an assured position it must have passed successfully through an evolutionary period of longer or shorter duration. But a small percentage survived the ordeal and almost none could pass through unchanged, and this, it seemed, would be the case with the theory of vaccine therapy. It would undoubtedly survive, but it had already undergone very considerable modifications. The great mass of data resulting from the indiscriminate experiments during the first stage of enthusiasm was now sifted and it began to be realized that the method had decided limitations and was by no means suitable for every case. This was the first step toward a fuller understanding. The cases to be treated by vaccines were now selected with greater care and the authors felt justified in assuming that while vaccine therapy was undoubtedly a step in the right direction, the results obtained, considered as a whole and from all points of view, were not sufficiently superior to recommend the complete abandonment of the older well-tried methods. The results seemed to show rather that we should avail ourselves of this new therapeutic agent as a powerful adjuvant to other methods rather than as a specific. It might be that in the future our knowledge of the exact meaning of the vaccine action would be sufficiently enlarged to enable us to advance still further along the line in vaccine therapy.

Dr. James Nevins Hyde of Chicago said that in connection with their work with the vaccines he could at least say that so far as he knew no harm had been done in any instance, which was something. The results they had obtained were in some instances brilliant, especially with the autogenous vaccines; at other times they were disappointing. In severe cases of sycosis their results had been very good indeed; in sycosis vulgaris, which tended toward the lupoid type, we had at times to deal with a very obstinate disease, and in those cases he knew of no remedial measure that had produced better results than the autogenous vaccines.

Dr. L. Duncan Bulkley of New York said that while he could not deny the favorable reports that he had heard and the few that he had seen following this comparatively new method of treatment, he still held that there was a more important underlying factor than the mere skin manifestation, and that when the skin was in proper condition these various microorganisms would not be able to make any headway. Only temporary benefit could be expected as the result of this vaccine treatment, and in all recurrent lesions we must look for the disturbance in metabolism which lay at the bottom of the trouble.

Dr. Samuel Sherwell of Brooklyn said he would follow with the keenest attention the future history and development of vaccine therapy and he would be pleased to see dermatology progress in this as in other directions.

Dr. J. A. Fordyce of New York said he was a believer in the future of vaccine and serum therapy, and he thought that the failures that had been reported were traceable to an imperfect knowledge of the technique. The collaboration of the clinician and the laboratory worker would doubtless result in improvements in this method of treatment. In sycosis, the speaker said, autogenous and stock vaccines had been used with indifferent results, and local treatment with epilation was usually employed in conjunction. In chronic furunculosis the vaccines had given him good results.

Dr. M. B. Hartzell of Philadelphia said the evidence which was obtained by injecting these various bacillary mixtures in diseases like erythema multiforme and pityriasis rosea, which would have gotten well without any treatment, was of no value. To prove the worth of these remedies they must not be used in cases that were self-limited. The speaker said he did not wish to be understood as denying the possible value of the vaccine treatment; he believed that the principle underlying the method had a great deal in it, but we still had much to learn as to the technique, and so far as his own observation and experience went the results thus far had been extremely unsatisfactory.

Dr. James M. Winfield of Brooklyn said he had used the vaccine treatment in general furunculosis with marked improvement in every instance. He had had no results whatever from the treatment in sycosis, and since listening to Dr. Engman's paper he had come to the conclusion that the cause of the failure lay in the technique. In the future he would follow the plan of pulling out the hair, thus irritating the nodule and causing a flow of lymph, and see if the results were not better.

Dr. Gilchrist in closing said his paper simply gave the results of a large amount of experimental work in connection with vaccine therapy. The treatment was tried in skin eruptions of which the cause was known; it was tried in cases in which we thought we knew the cause, and, lastly, it was tried in cases in which we were entirely ignorant of the cause. In the treatment of all these conditions two definite objects were sought: First, to raise the resisting power of the individual by regulating the bodily functions by diet, fresh air, etc., and, second, to find a specific treatment for the disease. Both of these phases of treatment were equally valuable.

Dr. Engman in closing said that in discussing such subjects as this we must remember that we were dealing with the great laws of immunity, of which, at the present date, there was much to be learned. When Wright brought forth his opsonic theory he made a great discovery, and out of that had come the vaccine theory which opened many unexplained fields. The only way we could arrive at any conclusions regarding it was to experiment with vaccines and bacterial suspensions in a large number of cases. Theoretically the treatment should only be used in the cases from which the vaccines were grown. We should not employ too large doses and we should endeavor to perfect our technique.

Pellagra in Ohio.—By Dr. William T. Corlett and Dr. Oscar T. Schultz of Cleveland. The authors stated that following the awakening that pellagra existed in this country many pseudo cases were brought to the attention of experts in cutaneous medicine. The paper then gave a brief history of one of these cases seen in Ohio where the patient was supposed to have contracted the disease from "corn smut." In the opinion of one of the writers this case was nothing more than an obstinate form of eczema. An investigation of supposed epidemics of some unknown disease of the skin in two of the State hospitals for the insane in Ohio revealed nothing unusual. All doubt as to the presence of pellagra in this country was removed, however, on visiting the hospital for the insane at Peoria, Ill. The authors then gave in detail the history of the first case of this disease recognized in Ohio, with photographs of the skin lesions, post-mortem findings, and histology. It was thought, in conclusion, that the disease, while not wholly confined to certain regions

of this country, yet its limitation was fairly well defined and that from the testimony of those who had seen most of the affection in this country it was not entirely new.

Dr. James W. Babcock, superintendent of the State Hospital for the Insane at Columbia, S. C., and president of the National Pellagra Congress, said he understood that there was considerable skepticism in regard to the existence of pellagra in this country, and it was only those who had served in public institutions, particularly in the Southern States, and who had been face to face with this condition for years, who could comprehend the importance of having more light shed on this mysterious malady. A year ago a conservative estimate of the number of pellagrins in the United States placed the number at 1,500; recently the figures had been gone over, and it now appeared that the disease had been recognized in twenty-seven or twenty-eight States. Cases had been reported in two hospitals in Illinois and subsequently in a third, and it had been shown beyond the shadow of a doubt that the disease existed in some of the western States, including California, so that we now had come to the conclusion that it had a very widespread distribution. Dr. Babcock said that from personal investigation and inuiry he was satisfied that pellagra had existed in South Carolina for nineteen years at least, and there were traditions of cases that went back as far as 1870. In reply to a question as to the mortality of the disease the speaker said that in one insane asylum for white people in the South where they had observed the disease since 1896 they had twenty-seven cases, with eighteen deaths. The mortality, according to different observers in the South, varied anywhere from 40 to 70 per cent.

Dr. James Nevins Hyde of Chicago showed an original copy of a volume entitled "Historia Natural y Medica," by Dr. Gaspar Casal, which was published in Madrid in 1762, and which, so far as was known, was the first contribution to the subject of pellagra. Dr. Samuel Sherwell of Brooklyn was properly credited with having made the first contribution on this subject to the American Dermatological Association. This was in 1882.

Dr. Howard Fox of New York referred to his work in experimental serum therapy in pellagra and regretted that he was not yet prepared to present a paper on that subject.

Dr. S. Sherwell of Brooklyn said the case referred to by Dr. Hyde was published in the *Journal for Cutaneous and Venereal Diseases,* in February, 1883. The patient was an Italian sailor, with both subjective and objective symptoms, forming together a classical picture of the disease. Two years later a similar case presented itself at his clinic, almost or quite identical to the first. Both cases ended fatally.

Dr. H. W. Stelwagon of Philadelphia said that several European observers who had studied this disease had made the observation that pellagra had occurred in persons who had never eaten corn. Among this number was Kaposi, and, he believed, Besnier also.

Dr. Sherwell thought that the fungus or parasite to which pellagra had been attributed might occur in all cereals analogous to corn, such as rye, etc.

Dr. M. B. Hartzell of Philadelphia reported a case of apparently typical pellagra occurring in a subject who had never been outside the State of Pennsylvania, and who, so far as could be ascertained, had never eaten Indian corn.

Dr. Louis A. Duhring of Philadelphia believed that the causative factor of pellagra was distinctly internal, and probably of a toxic nature.

Dr. William A. Pusey of Chicago, speaking of the exclusion of corn from the diet, said that when it came to the statement that a patient in this country had never eaten Indian corn, the reliability of such a statement could be seriously questioned. The statement was analogous to the contention of Jonathan Hutchinson in regard to the relation between leprosy and eating fish; Hutchinson was always prepared to prove that any one had eaten fish. Dr. Pusey said that while we had made an important advance in recognizing the presence of pellagra in this country, he was inclined to believe that the diagnosis was now being overworked. Pellagra was not a condition in which we could make as satisfactory a diagnosis as we could in tuberculosis or syphilis; the diagnosis rested on a triad of symptoms—psychical, gastrointestinal, and cutaneous. It was essentially a picture of autointoxication, such as we met with in gastrointestinal disturbances, and he believed that many of the cases of so-called pellagra might well be questioned as to the accuracy of the diagnosis.

Prurigo, and the Papule with the Urticarial Basis.—By Dr. O. H. Holder of New York. This paper embraced an anatomical study of the pale papule of prurigo.

Some Problems in Metabolism Occurring in Patients with Certain Diseases of the Skin.—Dr. L. Duncan Bulkley of New York said that faulty metabolism was recognized as a cause of many diseases; it might affect all the body tissues, and it was natural to expect that the skin participated. While definite and specific statements could not yet be made as to the exact and particular metabolic derangements belonging to various diseases of the skin, there were abundant clinical evidences that the cellular derangements which constituted the bottom fact in skin lesions had an intimate connection with and dependence upon metabolic errors. The urine, coming directly from the arterial blood, furnished a most suitable indication of the condition of the blood as it had been prepared through metabolism; consequently, repeated, careful volumetric analyses of its constituents furnished the most certain method of determining the performances of anabolism and catabolism in the tissues.

Dr. Louis A. Duhring of Philadelphia said that this subject of metabolism in relation to diseases of the skin had interested him for many years, and he had long since ceased to study and treat diseases of the skin—as he did years ago—from the standpoint of the lesions alone. If we wished to permanently cure many of the skin lesions, we must study the patient and conditions within the body. He had long been dissatisfied with the usual local treatment in a large number of chronic inflammatory diseases of the skin.

Dr. King Smith of Toronto said that Dr. Sims Wood of London, England, in an address before the students of the Toronto University, had laid great stress upon the close relationship between the men who worked in the laboratory and the clinicians.

Dr. M. B. Hartzell of Philadelphia asked Dr. Bulkley if he controlled the results he obtained by comparing them with the urinary findings in those who had no skin eruptions? The speaker said he was convinced that such a comparison would show just as wide variations in one as in the other.

Dr. S. Pollitzer of New York said that while quantitative analyses of the urine might be very useful, they did not constitute studies in metabolism. In fact, they were utterly worthless for that purpose unless at the same time the diet of the patient was controlled and the intake and output compared.

Dr. Bulkley, in closing, reiterated his belief that faulty metabolism was an important factor in connection with diseases of the skin.

Secondary Eczema.—Dr. John A. Fordyce of New York, in his paper on this subject, stated that in observing a large number of cases of dermatitis in hospital and dispensary practice, he had been struck with the frequency

with which forms of skin infection which were usually diagnosed as eczema had been secondary to some antecedent lesion or disease of the skin, such as scabies, wounds, or traumatisms which had become infected, abscesses, furuncles, intertrigos, sinuses left after operations on bones, etc.; in other words, the percentage of eczemas in which some antecedent pathological condition could not be determined seemed to be in the minority. From an extensive experience with cases of eczematoid dermatitis in which a history of antecedent pus infection was obtained, the conviction had come to him that irritation of the skin produced by discharges from abscesses, sinuses, ulcers, and other pus secreting surfaces was the true basis of these phenomena. This irritation might be followed by eruptions of most diverse forms, such as a dry scaling dermatitis or large moist areas, or a combination of dry scaling lesions and moist and crusted ones. Sometimes the picture was that of an acute vesicular eczema, and could not be distinguished from the usual forms of eczema which had been attributed to some internal disturbance. In all or most of these forms the affection was distinctly autoinoculable, and in many a condition of chronic eczema or dermatitis persisted for months or years. There might or might not be relapses; in many cases recovery was permanent. On the other hand, with a lowered resistance to pus infection, recurrences took place as furuncles and abscesses, with a subsequent eczema. One of the most prominent features in many patients with eczema was the increased susceptibility which their skin presented either from the beginning or which developed as the process progressed. It was this heightened susceptibility which led to relapses, as was often seen in workers in chemical laboratories in whom the vapor of formaldehyde provoked forms of dermatitis of the nature of eczema. The same condition was seen in individuals who had once developed dermatitis from poison ivy or other local irritant: after one attack many of these people were increasingly susceptible to the specific irritant, and it was quite possible in these cases to attribute the frequent recurrences to a state of anaphylaxis. Individuals who showed such an increased susceptibility to irritants might perhaps be sensitized to the chemical products of pus organisms, just as patients with tuberculosis might be sensitized to tuberculin. Assuming, therefore, that we might have a state of hypersusceptibility to irritants which might be present either from birth or acquired from some change in the biological properties of the blood serum due to various affections, we could readily understand how irritants of the most varied kind might evoke a dermatitis. These serological changes might also explain the simultaneous or successive occurrence of skin and mucous membrane affections in patients who had become sensitized with an irritant, in the one case acting on the neurovascular apparatus of the skin and in the other on the mucosa.

Dr. Martin F. Engman of St. Louis said that Dr. Fordyce, in his paper, had opened up a field which showed the way to a great deal of valuable work.

Dr. M. B. Hartzell said he was quite convinced that in a certain number of cases there was a local sensitizing of the skin. We found certain eruptions in certain localities again and again in certain individuals who at first showed no such sensitiveness to such irritating agents.

A Fatal Case of Bullous Dermatitis.—Dr. S. Pollitzer reported this case, which he summarized as follows: The patient was a middle-aged man, of good habits, in good health, except for a chronic diffuse nephritis which apparently gave no trouble. He was attacked with a dermatitis that had the character of a fine, scaling pruritic erythrodermia, and that rapidly spread over the entire integument. Its development was in some places preceded or accompanied by a severe edema, which subsequently subsided, but a moderate edema of the entire surface persisted for two weeks. Ten days after the appearance of the scaling red areas crops of large bullæ appeared in various parts of the body, but mainly on the extremities and the buttocks. The development of fresh blisters, in general smaller than at first, continued in greater or less number throughout the course of the illness, and the skin became diffusely pigmented. Temperatures following a septic curve up to about 104° developed, the patient became delirious and fell into a typhoidal state which terminated after a fortnight in coma and death, the whole course of the illness lasting about forty days. The blood showed at first an extraordinary eosinophilia, which later assumed moderate proportions. Blood cultures, cultures from the blister serum and inoculations from the latter were negative, as was also the examination of the illuminated dark field. The post-mortem examination threw no light on the case. As to the diagnosis of this remarkable case, it might be said that we were certainly not dealing with a pemphigus, as modern usage limited that term to a disease which was primarily bullous. The acute form of pemphigus, which alone could come under consideration in this connection, might be excluded by the absence of any infected wound, and, above all, by the preliminary diffuse scaling.

Dr. J. A. Fordyce of New York spoke of a case similar to the one reported by Dr. Pollitzer, excepting that there was no history of any antecedent eruption. The case also ended fatally. The etiological factor in these cases, the speaker said, was still unknown. It was perhaps some obscure proteid or a chemical product.

Dr. Duhring said it seemed to him that whatever the cutaneous lesion might be at the outset, the condition often or generally developed into what might properly be termed pemphigus, and he could see no objection to classifying it as a case of pemphigus malignus.

Dr. James Nevins Hyde of Chicago said the case reported by Dr. Pollitzer was a commentary upon our occasional impotence and lack of knowledge. Here we had an interesting and fatal case reported under a title which referred to a condition of the skin merely, and yet the symptoms showed that we were obviously confronted with some toxic process which profoundly influenced the entire economy and of which the skin lesions were simply the superficial evidence of the deeper trouble.

Dr. Pollitzer, in closing, said that in pemphigus malignus or acutus, to which Dr. Duhring had referred, there was usually a history of preceding injury, followed either immediately or in the course of a few days by an acute septic condition, with the formation of bullous lesions on the skin. There was no history or evidence of such a condition in this case.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held May 26, 1910.

Dr. S. M. Brickner in the Chair.

A Case of Complete Absence of the Vagina and Uterus in an Otherwise Normal Woman.—Dr. Meyer Frankel presented a patient, twenty-five years old, who had been married two years. She had a sister who had not menstruated although she was now sixteen years of age. The patient had always enjoyed perfect health, but had never menstruated. When nineteen years old she consulted a physician because of the fact that she had never been unwell. An operation was performed and she was told that she might marry. Her chief complaint was severe pain on intercourse. An examination revealed a complete absence of vagina and uterus. The clitoris was present and the woman had a desire for intercourse. During her two years of married life, the husband had at-

tempted intercourse and, during his orgasm, the semen was injected into the bladder; this caused the sphincter of this organ to become overdistended, and lowered its tonicity to such an extent that the patient could not retain her urine. After keeping the husband apart from her for six months, the tonicity of the sphincter was regained and she could now retain her water. Dr. Frankel asked if there had been reported any cases of artificial vagina made by intestinal transplantation, such as had been reported by Dr. J. F. Baldwin of Columbus, Ohio. No member present was familiar with any such instances.

Chorioepithelioma.—Dr. Louis J. Ladinski presented this specimen. The patient was a woman, forty-six years old, married twenty-eight years. She had had ten children, the last seven years ago. She had never aborted. Menstruation had begun at the age of fifteen years; it had been regular, lasting for from seven to ten days. About a year ago her abdomen began to increase in size and she had irregular spotting and bleeding. She had been curetted, after which the bleeding stopped and did not recur until about three months ago. She began at that time to have pains in the right iliac region, marked weakness, anemia, and slight cough. At the time of admission to the hospital she also had slight edema of the lower extremities. There were subcrepitant râles over the right apex of the lungs posteriorly. The uterus was enlarged to about the side of a two months gravid uterus. The anterior and lateral walls were normal in consistency, but there was a boggy mass in the left lateral wall about the size of a hen's egg. The cervix was eroded and lacerated. A diagnosis of uterine myoma was made. At operation a soft tumor was found at the left of the uterus, intimately adherent to the left side of that organ and extending to the broad ligament subperitoneally. The ovary laid posteriorly and the Fallopian tube was stretched across its upper and anterior surface. A supravaginal hysterectomy was performed. On the second day following the operation she expectorated a large amount of bloody sputum in which was found a large number of Lenhard cells. There was an infiltration of both lower lobes, not miliary in character. The mediastinum was involved as well. The pathologist reported this to be a case of chorioepithelioma, and the curettings showed the presence of a chronic endometritis.

Carcinoma of the Ovary.—Dr. Louis J. Ladinski presented this specimen, a solid carcinoma of the ovary.

Complete Absence of Vagina; Pregnancy; Rupture of Uterus.—Dr. Louis J. Ladinski presented this patient who was twenty-three years old. This was a case in which there was a complete absence of the vagina. The cervix extended down to the introitus vaginam. The dilated os serves for the entrance of the vagina, and the cervical canal for a substitute vagina.

Carcinoma of the Cervix on the Border Line of Operability.—Dr. Herman J. Boldt presented this specimen. The patient was sixty-five years old, and had had three children, the last twenty-eight years ago. The broad ligaments were involved slightly beyond their attachments to the cervix. A radical operation was performed. While Dr. Boldt had operated upon a number of patients with cancer on the border line of operability and, as a rule, with recovery from operation, yet he did not believe this to be good surgery to attempt the radical operation; the patient's interest was better served if a palliative operation was performed. This was almost devoid of danger, and the lives of such patients were usually prolonged from one to three years.

Cancer of the Cervix; Extirpation by the Abdominal Route.—Dr. Herman J. Boldt presented this specimen. The patient was forty-two years old. The statement was made that the broad ligament infiltration was inflammatory and was not caused by the malignant disease. It had frequently been stated that such a differentiation could not be made. In this case, however, he thought it was fair to assume that there was a probability of its being the result of inflammation. He called attention to the necessity of invariably making a positive diagnosis in all suspicious cases. Dr. Boldt also furnished the following specimens:

Myofibromata Complicated with Carcinoma of the Corpus Uteri.—Because of its being a corporal carcinoma, and because of the unusual obesity of the woman, a vaginal hysterectomy was performed.

Complicated Hystero-Salpingectomies.—Dr. Boldt believed there was no class of abdominal operation that was more difficult to do, from a technical point of view, than these old pyosalpinx cases. As a rule, however, there was no class of patients that one might get a more satisfactory symptomatic cure than in such conditions. The prognosis was very good, and this he ascribed to the tolerance of the peritoneum in such cases.

Myofibroma Removed by Extensive Myomectomy.—The patient was thirty-two years old. The tumor encroached so extensively on the uterus that the larger part of the anterior uterine wall had to be removed with the tumor. It would be interesting to watch this patient in the event of a subsequent pregnancy. It was likely that in the case of conception, an abortion or a premature delivery would take place.

Myomatous Uterus with Adnexa Removed by the Abdominal Route.—The sole object in presenting this specimen, Dr. Boldt said, was to object to the removal of the ovaries from a patient thirty-five years old; a functionating ovary should always be retained whenever feasible. In this instance an exception was made to his customary rule of retaining the ovaries in fibromyomatous tumors because of the constant pain complained of in the region of the ovaries.

Submucous Myofibroma and Tubal Pregnancy.—This patient was forty-one years old, married nineteen years, and she had had three children, the last nine years ago. The feature of interest in this case was the diagnosis; this should have been easy if one had thought of the two conditions as occurring together instead of attributing the symptoms to the myoma alone.

Report of a Case of Hysterectomy and Extirpation of Thrombosed Veins in Sepsis Following Abortion.—Dr. Gustav Seligman presented this specimen. The patient was admitted to the hospital April 14 in a septic condition which followed an incomplete abortion. On April 23 he found a distinct doughy mass corresponding to the right broad ligament and he made a diagnosis of thrombosis of the uterine plexus of that side. His diagnosis was confirmed by operation, the thrombosis extending to and beyond the internal iliac vein and into the common iliac. The infected province was extirpated.

Eclampsia and Its Treatment with Continuous Sugar Instillations.—Dr. Sidney D. Jacobson said that the path of medical progress was literally strewn with disproved theories and abandoned dogmas; the scientific facts of yesterday were the exploded theories of to-day. The etiology of eclampsia had not as yet been determined. Dr. Jacobson was convinced, however, that the cause of puerperal eclampsia in a pregnant woman, or one recently delivered, was nephritis. Furthermore, that the cause of eclampsia was insufficiency of the kidneys due to a nephritis, whereby an accumulation of the salts normally found in the blood occurred. This retention in the blood of these salts raised the molecular concentration and specific gravity of the blood, until convulsions occurred. The all important thing was to reduce the high concentration and specific gravity of the blood whether convulsions had occurred or not. For this purpose the usual salt solution was contraindicated because the patient was dying from too much salt in her blood. Dr. Jacobson found

that a solution of sugar, 0.5 of 1 per cent. at 115° F. per rectum, continuously, by the drop (Murphy) method had the desired effect. The specific gravity of the patient's blood was reduced perhaps from 1,060 to 1,052; she perspired freely; her urine increased greatly in quantity; the sensorium, if clouded, became clear and she started on her way to recovery. The convulsions ceased. Of several cases treated by this method, all the mothers and babies recovered. Besides giving the sugar instillations, other adjuvants to treatment were not neglected. He believed that the keynote of success in the treatment of puerperal eclampsia was to dilute the patient's blood, reduce its excessive molecular concentration and high specific gravity, by washing the retained salts out of the system and, therefore, continuous rectal administration of hot sugar water was the most important curative method of treatment.

The Surgical Treatment of Vaginal Delivery.—Dr. Edward P. Davis of Philadelphia read this paper. He called attention to the fact that when antisepsis and asepsis were adopted obstetric surgery was the last branch to develop under these new conditions. Success in abdominal surgery had led to the revival of cesarean section and antisepsis had made symphyseotomy possible with better results than had previously been attained. Vaginal cesarean section had been added to the list of operations and suprasymphyseal section was now under consideration. The success of these operations depended not only upon antisepsis and asepsis but upon the application of surgical principles to the management of parturition. The two foes which the surgeon dreaded were hemorrhage and septic infection and no operation was complete which did not leave the patient's tissues as thoroughly repaired as her vital condition would permit. In the various forms of cesarean section upon uninfected patients the operator usually closed all wounds and usually obtained primary union. Upon infected patients the Porro operation and the suprasymphyseal uterine fistula carried out the surgical principle of drainage. Vaginal delivery by forceps, version and extraction or craniotomy had not been carried out under surgical principles as had the major operations. The main object of his paper, Dr. Davis said, was to record some of his experiences in the surgical treatment of vaginal delivery and to elicit discussion on this point. It was obvious that they were not discussing normal labor. Nature's mechanism against hemorrhage and infection in normal labor, was so perfect that nothing but a positive indication should lead to interference. A hemorrhage often followed uterine relaxation, and this was caused by exhaustion; the patient should not be allowed to become exhausted. A correct diagnosis of the comparative size of mother and child and the mechanism of labor present would prevent the fatal delay in impossible labor. In the patients who became exhausted early in the second stage of labor, dilatation of the cervix and vagina by bags was successful in many cases, while in some it caused suffering, converted a favorable to an unfavorable mechanism and predisposed to exhaustion. Manual dilatation under ether preceding delivery was often more efficient and less distressing and exhausting to the patient. The necessity for the immediate removal of the placenta might not always be present and the patient might be allowed to come partly from the influence of ether, when, under tonic doses of strychnine and ergot given hypodermically, the uterus would contract sufficiently to detach the placenta. Should partial separation of the placenta occur with hemorrhage, the placenta should be immediately separated and delivered by the gloved hand. Dr. Davis said that, in his experience, it was safer, under antiseptic precautions, to take measures to prevent relaxation of the uterus than to omit these precautions and some time later to treat postpartum hemorrhage. Where relaxation might reasonably be expected, and hemorrhage feared, the emptying of the uterus should be followed by irrigation with salt solution, or with one per cent. lysol, and thorough tamponing of the cavity with 10 per cent. iodoform gauze. Where more than one assistant was present the two lips of the cervix might be grasped separately by tenaculum forceps, drawn down to the vulva and the packing done under direct vision. Or, the left hand of the operator might be introduced within the vagina at the cervix, the fundus being brought downward and forward by the hand of the anesthetizer placed upon the abdomen. The gauze was then introduced with dressing forceps. He called attention to the danger of tamponing the lower section of the uterus only. Hemorrhage from the body of the womb was usually promptly controlled by this method. In cases of extreme exhaustion the gauze might be wrung out of adrenalin, 1:100 and then introduced. The risk of septic infection or of perforation of the uterus was less with this method than that of treating postpartum hemorrhage an indefinite time after labor by hot douching, the introduction of vinegar, and the attempt to tampon the uterus when the patient was not under an anesthetic. For some time they had made it a rule to immediately suture, when the vital condition of the patient permitted it, lacerations of the cervix extending nearly or to the vaginal junction. They had done this in several hundred cases and a few years ago they had obtained 80 per cent. of complete primary union of the cervix after immediate suture, 10 per cent. of partial union and 10 per cent. of failures. In none of these cases did infection occur. The preliminary uterine packing with gauze was employed in these cases whenever laceration was extensive. They did not attempt a complete restoration to the condition of the unimpregnated cervix, nor did they believe that such restoration was of practical value to the woman liable to repeated parturition. The cervix should be closed to within half an inch, or in favorable cases a quarter of an inch of the external os. In cases of severe laceration through the cervix and into the fascia of the posterior segment of the pelvic floor, the closure of the upper extremity of such laceration was of special importance. The stitches might embrace some of the tissue forming the sacral ligaments, and by restoring the parts, tended to draw the cervix backward and thus prevent retroversion. Tears in the sulci and fascia of the levator ani muscle were of primary importance and next came the sphincter and its surrounding fascia. When these had received attention the perineum might be closed in such a way as to carry the posterior vaginal wall upward and backward, thus preventing rectocele and prolapse. Lacerations of the anterior segment should not be neglected. Difficult vaginal deliveries should, if possible, be conducted in hospitals. Primiparous patients should, as a rule, be confined in hospitals.

The number of women who sought hospital care was constantly increasing and no general hospital with facilities for surgical work should hesitate to receive confinement cases. In private houses the operator must transport sufficient appliances to establish and maintain antisepsis and aseptic technique. The anesthetizer was considered a most important assistant and in addition to the nurse who had charge of the patient there should be one who gave her time to preparation of dressings and supplies and the care of instruments, etc. This nurse was provided with sterile gloves and a sterile gown. While the external parts were prepared with soap, sterile water and bichloride, they limited vaginal douching to a single irrigation with lysol, one per cent. After delivery the uterus and vagina were thoroughly but gently irrigated with one per cent. lysol and in addition to the uterine tamponing the vagina was moderately tamponed with bichloride gauze. The gauze was removed forty-eight hours after delivery, and the genital tract irrigated with one per cent.

lysol. No other douches were given during the puerperal period. Dilute bichloride solution or lysol was poured over the stitches as often as necessary. To maintain a tonic condition of the uterine muscle, strychnia and ergot were given through the first week or ten days of the puerperal period. In private patients he had had two failures in closure of the pelvic floor, in both of these the stitches in the sphincter and its fascia were torn out during the first week, because the patient strained during movement of the bowels. Other than these there had been no complications in these cases. Dr. Davis urged that in all cases of vaginal delivery in which lacerations occurred and in which hemorrhage and sepsis threatened be treated upon surgical principles.

Dr. Edwin B. Cragin believed that what was recommended by Dr. Davis was the work of an expert and not of the general practitioner. While the immediate repair of a lacerated cervix might be the proper thing to do in hospitals where they had proper facilities, it was not a good procedure for the general practitioner. He taught his student that, unless there was hemorrhage present, it was wiser not to attempt an immediate repair of a lacterated cervix; the woman's condition was made far safer if the practitioner kept his hands away from the vagina.

Dr. Robert L. Dickinson did not believe that the general practitioner should tampon the uterus with impunity. Except in cases of hemorrhage the lacerated cervix should not be immediately repaired. The best time to repair a lacerated cervix was four, five or eight days after labor when the anatomy of the parts could be made out more readily. A uterine tampon should not be left in longer than eight or twelve hours.

Dr. J. Clifton Edgar did not believe that students should be taught that it was necessary to repair a lacerated cervix immediately. Gauze should never be left in the uterus longer than twenty-four hours.

Dr. Herman J. Boldt said it was a great omission on the part of any physician to allow a woman whom he had confined to go without a subsequent examination to determine whether she had a laceration and, if so, how extensive it was. A lacerated cervix should be repaired one or two weeks after labor.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of October 8, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	511	155
Diphtheria	202	20
Measles	53	3
Scarlet Fever	77	4
Smallpox	—	—
Varicella	35	—
Typhoid Fever	143	17
Whooping Cough	33	5
Cerebrospinal Meningitis	4	7
Malarial Fever	—	—
Totals	1,058	211

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended October 7, 1910.

POST-PROSTATIC CYSTOTOMY.*

BY EUGENE FULLER, M.D.,

NEW YORK.

IN the operation known as perineal cystotomy, a procedure long and universally employed, the incision through the perineum lays open the posterior or deep portion of the membranous urethra, after which the prostatic urethra or vesical neck is incised on its floor sufficiently to allow digital or instrumental access to the bladder cavity, and it is along this tract that the usual urinary drainage tube is passed and maintained as a surgical feature in the after treatment of that operation. Previous to 1880, when Garson and Peterson revived the operation of suprapubic cystotomy by demonstrating its operative practicability and great advantages, the old operation just described of perineal cystotomy or the modification of it employed in the operation known as lateral perineal lithotomy was the only route used for the accomplishment of intravesical surgical procedure or for the establishment of vesical drainage.

The operation which I now formally introduce to the profession and at the same time assign a place of surgical usefulness and value is in the nature of a perineal cystotomy in that it is through the perineal structures that the surface dissection is made. It differs, however, radically in all other respects from the ordinary perineal cystotomy in that no portion of the deep urethra or vesical neck is disturbed or entered. The deep path of the perineal dissection in the operation I am introducing lies behind the prostate, extending between that structure and the rectum and enters the bladder through a longitudinal incision in the floor of that cavity. This vesical incision bifurcates the V-shaped space formed by the approximation of the ampullæ of Henle, the term applied to designate the clubbed ends of the vasa defferentia. The incision described intravesically extends from the middle portion of the vesical floor forward midway between the ureteral orifices and divides the posterior limit of the trigonum. I have named this procedure Post-Prostatic Cystotomy. For the development and the trial of this operation of post-prostatic cystotomy I am indebted wholly to my operation of seminal vesiculotomy. In fact, I consider this cystotomy operation an extension, as it were, of my operative work in connection with the seminal vesicles. Through much experience with seminal vesiculotomy I found occasionally, owing to diseased or faulty conditions of the vesical floor lying over or about the seminal vesicles, that more or less urine leakage occurred along the tract of the incision in the after treatment of that operation. In no such instances, however, did this urine leakage serve to complicate or interfere with the final result of those operations. In all these cases also the urine leakage spontaneously ceased with the healing of the seminal vesiculotomy incision and in none of them were there any resulting vesical disturbances attributable to the accidental leakage. Finally during the performance of a seminal vesiculotomy in which a post-prostatic vesical sacculus or pouch existed, the wall of which was very attentuated, I accidentally incised this sacculus, thus making a free incision into the floor of the bladder. After completing the seminal vesiculotomy a 30 French soft rubber catheter was passed along the tract of that incision and through the opening in the bladder floor and maintained there for vesical drainage for eight days. The presence of the vesical drainage tube caused the patient very little discomfort and no vesical tenesmus, such as one would commonly expect in connection with a tube worn for that length of time in the after treatment of an ordinary perineal cystotomy. After the removal of the tube the vesical and the perineal wound soon healed and there was no resulting bladder disturbance. This experience naturally made me wonder whether the deliberate rather than the accidental performance of such a cystotomy might not be advisable in certain bladder conditions. In fact, I felt that a cystotomy associated with so little disturbance to the patient had much to recommend it and might well be found to be the operation of choice in some cases. On giving thought to the subject it is easy to appreciate that a post-prostatic cystotomy gives the most perfect and dependent vesical drainage while a patient lies on his back in bed, the customary position assumed after operation, and in this particular has a special advantage over the suprapubic operation and a considerable one over the ordinary perineal cystotomy. In common with the suprapubic operation, it avoids a surgical disturbance of the deep urethra or of the neck of the bladder. In taking up the study of the field of usefulness open to this operation of post-prostatic cystotomy it is first well to recall the diseased vesical conditions wherein neither ordinary perineal nor suprapubic cystotomy have seemed satisfactory forms of procedure. In June, 1906, before the American Urological Association (*American Journal of Urology*, December, 1906) I read a paper entitled "Operative Cure for a Hitherto Unrelieved Class of Cystites," in which I made the following statement: "In the early performance of seminal vesiculotomy the operation was undertaken for the relief of the usual symptoms, chiefly of a sexual nature, which accompany chronic inflammatory involvement of the seminal vesicles. In the study of the results in these cases I found incidentally that in a number of them symptoms of cystitis, which had coexisted with those of a sexual nature, spontaneously disappeared after convalescence from the operation. This fact led me to make a careful

*The president's address to the American Urological Association, June 6, 1910, St. Louis meeting.

cystoscopic study of the bladder in a series of cases of seminal vesiculitis. I found as a result that in those of them where the bladder was involved the lesion was confined to the base of the organ; in fact, to that part of the structure lying over the seminal vesicles. In some of them where the inflammation about the seminal vesicles had been extensive I found likewise that the inflammation invading the base of the bladder had been extensive and had extended further than the underlying portions of the seminal vesicles. In all these cases the other portions of the bladder were normal or nearly so in appearance.

"From these cystoscopic studies it seemed reasonable to infer that the lesions of the vesical bases accounting for the cystites were really peripheral ones, the center foci for which were the infected seminal vesicles, the germs in the bladders having penetrated the intervening tissues from the cavities of the seminal vesicles. In other words, I classed the bladder inflammations as localized pericystites. In mild cases the cystoscope showed the vesical mucous membrane of the area involved red, infiltrated, and edematous, while in the severe types granulation tissue had in large measure taken the place of the mucous surface. Here and there on these granulations would be pus flocculi, films of inflammatory exudate, and spots of hemorrhage. In some of the advanced cases the least instrumental contact with the surface granulations was sufficient to provoke a fairly free hemorrhage. On one of them a triple-phosphate crustation had formed.

"As a result of these investigations I felt confident that a cure of this form of pericystitis would follow spontaneously after the operative elimination of the chronic infection in connection with the seminal vesicles. Acting on this conviction, I have cured through seminal vesiculotomy a number of these cases, all, in fact, on which I have so far operated."

In that paper the clinical details of four operative cases were given. Since that time my clinical experience with cases of this description has been large. In numerous of them which I have cured through seminal vesiculotomy multiple perineal and suprapubic cystotomies previously undertaken at the hands of other surgeons in the hope of relieving existing vesical distress had only served the purpose apparently of aggravating such conditions. In some of these cases post-prostatic abscesses had formed leaving sinuses connecting old cavities with the vesical floor. It was in these cases that more or less abundant urine leakage naturally occurred after seminal vesiculotomy into the tract of that operation. It is in connection with such cases and also in connection with those of a similar character wherein the cystoscope shows the secondary or resulting lesion at the vesical base to be extreme, the intravesical granulations, for instance, being dense, extensive and perhaps coated with phosphatic crustations, that the idea has occurred to me that dissection into and drainage of the extravesical primary focus of infection, associated with the operation of seminal vesiculotomy, might not be radical enough.

In some operative instances of this character, although marked relief as regards bladder symptoms quickly followed the seminal vesiculotomy, still it was months with some of them before all pus, bacteria, and the last bladder evidences finally subsided, while others of them disappeared from observation with some of these evidences still persisting. Consequently it has seemed to me desirable in these cases to treat the bladder itself more radically, to cut through its exposed floor, and to drain it post-prostatically, making, in other words, the cystotomy a feature of the seminal vesiculotomy. I have already put this idea successfully to practical use, as will be seen in the clinical recital which will follow.

There is another class of cystites which have been largely abandoned as far as ordinary or suprapubic cystotomy are concerned and these are the tubercular cases. Such cases, it seems to me, should always be handled most conservatively and in the great majority of instances treated hygienically and therapeutically rather than surgically. Still, in some of those cases where the element of vesical tenesmus is intense, and especially in those of them where phosphatic calculous crustations have formed on the ulcerated vesical surfaces, the surgeon may be impelled to attempt some relief through operation. In such instances suprapubic has been found preferable to perineal cystotomy since it avoids the neck of the bladder, the cutting through of which invites the ingrafting of the tubercular process on this part and a consequent exacerbation of tenesmus.

The disadvantage, however, of suprapubic cystotomy in these cases lies largely in the danger of a secondary tubercular infection and invasion of the space of Retzius associated with persisting suprapubic fistula. The suprapubic opening affords, as has been mentioned, very defective vesical drainage, and it is this feature which makes it very difficult in the after treatment of these cases to eliminate or keep in abeyance elements of mixed infection, which serve to stimulate the tubercular process and to aid it in extending itself both intravesically and also extravesically into the space of Retzius.

Post-prostatic cystotomy has the advantages of both the preceding operations without their disadvantages. It avoids the vesical neck and affords even better vesical drainage than the ordinary perineal cystotomy. It seems to me that this operation will be found of great benefit in these distressing conditions. The clinical experience to be detailed goes to substantiate this opinion. Suprapubic cystotomy in connection with thickened, contracted and non-distensible bladders is often a troublesome procedure, and after operation in such cases it may be very difficult to establish suprapubic vesical drainage. In some such cases as these, and especially in those of them where a fairly prolonged drainage of the bladder seems essential, it may be that the operation of post-prostatic cystotomy will be found especially applicable. As has already been stated, this operation, post-prostatic cystotomy, is an extension or development of my operation, seminal vesiculotomy. In other words, any surgeon who has familiarized himself with the latter operation will have no difficulty in the performance of the cystotomy.

In the dissection associated with seminal vesiculotomy the floor of the bladder is exposed, and that part being once exposed the matter of making the longitudinal incision through its floor is a simple and easy detail. In my last year's communication before this association entitled "Relief of Urinary and Genital Conditions Through Surgery of the Seminal Vesicles," a reprint of which appears in the 1909 transactions of the American Urological Association and also in the MEDICAL RECORD of New York, October 30, 1909, the operation of seminal vesiculotomy is carefully described and any one desirous of acquainting him-

self with post-prostatic cystotomy is advised to read that article in connection with this one.

Aside from my first experience with this operation, reference to which has already been made, the case being the one in which I accidentally cut through a vesical sacculus during the performance of a seminal vesiculotomy, I have successfully employed the procedure on two occasions. The clinical histories of these two successful cases are as follows:

Case A.—Man twenty-seven. His first gonorrhea, a very acute one, nine months ago. In the third or fourth week of the gonorrhea there was a history of threatened urinary retention and great tenesmus associated with severe perineal and rectal pain, together with fever. The threatened retention was suddenly relieved after five or six days associated with the prompt appearance of much pus in the urine and of a profuse flow of pus from the urethra. The tenesmus, the perineal and rectal pain and the fever all also quickly subsided with the relief of the threatened retention. The patient, however, had never recovered. A relapsing urethral discharge had persisted. Bacteria and pus had always remained in the urine. As the result of indiscretions or of exposure to cold, urinary urgency would become manifest, together with some tenesmus, which was more or less painful. At such times he was also subject to chills, followed by a febrile reaction. Seminal losses, which were somewhat frequent, were painful and were apt, he thought, to be followed by an exacerbation of the vesical tenesmus. Rectal examination showed a marked inflammatory involvement of the seminal vesicles and of the surrounding fibrous structures. In fact, the periseminal vesicular inflammation included most of the fibrous tissue area in the post-prostatic space. The floor of the bladder above the region of the seminal vesicles was edematous and granular, bleeding readily if touched by the end of the cystoscope.

It was evident in this case that first of all an acute gonorrheal seminal vesiculitis had occurred, followed by a periseminal vesicular abscess, which had pointed and discharged through the floor of the bladder. Post-prostatic cystotomy was performed, combined also with opening and drainage of the seminal vesicles. Two soft rubber catheters of 30 French caliber were introduced into the bladder side by side through the perineal incision and maintained there nine days for continuous drainage. Two tubes were used instead of one in order to facilitate vesical irrigation. On the ninth day some slight vesical intolerance of the tubes developed and they were removed. Ten days after their removal the perineal wound had thoroughly closed. A perfect operative result was promptly obtained in this case.

Case B.—Man twenty-eight years old. When first observed by me there was very frequent urination, associated with considerable vesical tenesmus. The urine was loaded with pus somewhat offensive as regards odor and slightly bloody. These symptoms had been gradually developing for over a year. Several years previously there had apparently been a gonorrheal infection, since which time the patient thought he had never been completely well. Rectal examination showed marked inflammation of the prostate and seminal vesicles. There was not much tenderness, however, to the touch, and the inflammation did not seem to the feel acute or recent. To use the cystoscope it was found necessary to put the patient profoundly under choloroform in order to allay the vesical tenesmus and adrenalin had also to be introduced into the bladder to check hemorrhage. It was then possible to get a view with the instrument. The whole interior of the bladder, but especially the base, was found to be the seat of lesions such as an extensive tuberculous process could present. There were areas of ulceration and others of proliferating granulations. The cystoscopic examination was quite disturbing and was followed by a considerable increase in the hematuria. The vesical tenesmus gradually increased after this until it became so pronounced as to be associated with complete incontinence. There was also continuous temperature. Tuberculin reactions were positive. The incontinence and the painful tenesmus rendered the patient's condition very distressing. Still, aside from prescribing creosote in large doses, I hesitated to do anything in the way of local surgical treatment, since the chance of affording even slight relief thereby seemed extremely small, while, on the other hand, the chance of increasing by such a course the patient's mental, if not his physical, discomfort appeared to be most probable.

After a time, however, a new symptom, that of rectal tenesmus, developed, and with it there was an increase in the range of temperature. Rectal examination then showed a soft boggy tumefaction which encroached in a marked degree on the rectal cavity from the post-prostatic area. It seemed evident that urinary extravasation had taken place into this space, the bladder floor having been perforated by the ulcerative tubercular process. If the case were now treated for a longer time expectantly, it seemed evident that a rectal perforation would soon follow. The resulting rectovesical fistula would certainly represent the acme of distress. Such an event should, if possible, be avoided, and for that purpose post-prostatic cystotomy was performed. In this instance, however, the seminal vesicles were not opened or disturbed, a free longitudinal incision only being made through the floor of the bladder. Two bladder drainage tubes were then introduced.

The operation in its immediate result was most gratifying both to me and to the patient. Rectal and vesical tenesmus ceased and the temperature fell so as not longer to be a factor. The tubes were retained in place ten days. The rectal feel then showed that all evidences of urinary extravasation had disappeared. The perineal wound soon closed to a narrow sinus. Most of the urine then came naturally. Blood disappeared from the urine. Incontinence to a large degree also disappeared and the patient might go from half to three-quarters of an hour without being called upon to urinate. At the end of six weeks fever in a marked degree returned and the patient began to fail from a general extension of his tuberculosis. Still, even then the local bladder discomfort was not nearly as marked as before the cystotomy. In this instance the post-prostatic cystotomy accomplished more than I had anticipated it would and certainly was well worth while. In another instance where the tuberculous process was not so virulent and rapid as in the present instance, much more should be expected from the operation.

252 Lexington Avenue.

MANIC DEPRESSIVE INSANITY AND DEMENTIA PRÆCOX.*

By CHARLES G. WAGNER, M.D.,

BINGHAMTON, N. Y.

SUPERINTENDENT BINGHAMTON STATE HOSPITAL.

Insanity is a disorder of the mental personality of an individual of far greater importance than any other ailment that can befall him. It changes his relationship with the entire external world in the most comprehensive manner. It deprives him of the power of self-control, robs him of his responsibility before the law and makes him at once a helpless wreck—wholly dependent upon others for all his wants, a menace to his own safety and a danger to others.

Mental derangement is responsible for one-third of the suicides, while sexual crimes, arson and assaults are also often committed by persons suffering from disordered minds. Many families are ruined by their afflicted members, either by the senseless squandering of their means or because long illness or inability to work exhausts their resources.

The great majority of insane persons live on for years and often become an increasing burden as the disease progresses. For these reasons and others which might be mentioned it is one of the physician's most important duties to make himself, to some extent, at least, familiar with the nature and phenomena of insanity. The object of this paper, however, is not to go deeply into the general etiology or symptomatology of mental diseases but rather to point out, in a limited way, some of the phases of the newer psychiatry as they are viewed by alienists at the present time.

For many years prior to a comparatively recent period writers on insanity classified the great majority of insane persons in one or another of four groups—the patients who exhibited mental or motor excitement, who were talkative and boisterous, now breaking suddenly into loud laughter, singing or shouting, now falling on their knees in prayer and, perhaps, a moment later springing to their feet with flashing eye and profane or abusive speech—the patients who, in a word, were *maniacal* were at once classed as cases of mania. If on the other hand they were emotional, depressed, and apprehensive, controlled by delusions of fear, or of having committed some unpardonable sin for which they must suffer through all eternity and, perhaps, with suicidal tendencies, again, in a word, if they were profoundly *melancholy*, they were with equal promptness classed as cases of melancholia.

The third group was made up of the patients who exhibited diminished mental activity, the feebleminded or *demented* patients, to them the name dementia was given. This term was used in an arbitrary way to signify general mental failure of a non-congenital type, unattended as a rule by active excitement.

A fourth form of insanity was denominated paranoia; this term was regularly used to indicate a chronic delusional and incurable form of mental derangement of long duration in which the delusions were usually persecutory in character, systematized around some dominant idea and gradually undergoing a process of evolution until a transformation of the individual's personality occurred and he imagined himself of exalted rank far above the station in life where he properly belonged.

*Read at the meeting of the Broome County Medical Society, held at Binghamton, N. Y., July 5, 1910.

These four forms and their subdivisions together with general paresis, epilepsy, and imbecility, were practically all that we formerly thought necessary in the way of classification for the study of our cases.

During the past twelve or fifteen years, however, our ideas in regard to all of these forms of insanity have undergone radical changes. The manias and melancholias which were once such clear and diametrically opposite pictures in our minds, we now find on closer study and more accurate analysis are but syndromes or symptom complexes of one fundamental disorder to which we give the name manic-depressive insanity—a mental disorder which at times appears as maniacal excitement, at other times as mental depression, and again as a mixed condition exhibiting symptoms of both mania and melancholia, with a tendency toward recovery without intellectual enfeeblement, and a tendency toward recurrence.

The conception of the manic-depressive psychosis or, manic-depressive insanity, is due to Kraepelin of Munich, and it undoubtedly constitutes one of the most important of the recent advances in psychiatry. Although the grouping together of such opposed and apparently different pathological states as melancholic depression and maniacal excitement may appear at first glance unreasonable, the soundness of this arrangement can scarcely be contested on closer observation and deeper insight into the nature of these syndromes. The conception of manic-depressive insanity, now generally accepted in this country as well as in Europe, is based upon two well-established facts; first, the existence of fundamental symptoms common to all manic-depressive states and, second, the alternation, more or less regular of excitement and of depression in the same individual. The fundamental symptoms referred to may be divided into two groups: the first group comprises all of the morbid phenomena dependent upon psychic paralysis, namely: (a) "Enfeeblement of the attention" which is easily distracted by all external impressions; (b) "Sluggishness of the association of ideas" shown by inability to calculate small sums or make a short narrative of well-known events, etc.; (c) "Insufficiency of perception" shown by illusions, and hypochondriacal ideas; (d) "Pathological indifference" shown by absence of emotion when painful circumstances are mentioned.

The symptoms of the second group are dependent, not upon the psychic inhibition but upon exaltation of the mental automatism. The principal symptoms of this group are: (a) Flight of ideas, or the rapid succession of representations which appear in the field of consciousness in great disorder; (b) "Morbid euphoria, diminished moral sense, irritability, and impulsive actions." These patients after recovery often say they never felt so well in their lives. On the other hand they are liable to violent outbursts of anger and to conspicuous moral lapses; (c) "Motor excitement"; (d) "Delusions, psychosensory disorders, fixed ideas and obsessions." All of these morbid phenomena are more or less constant symptoms in manic-depressive psychoses.

The close relationship existing between states of depression and maniacal states in these cases becomes still more evident, when, instead of considering a single attack we study all of the attacks that occur in the same individual. It is not common for a patient to have only one attack of mania or of

melancholia during his lifetime, so the idea of isolated, non-recurring attacks of mania or melancholia is almost eliminated. In some cases, it is true, we see several attacks of mania follow one another without intervening depression, but on the other hand we meet with other cases showing every gradation of transition between the two conditions so that the two groups apparently widely separated seem to be in reality identical. No matter how pronounced the melancholia or mania may be, close analysis will almost invariably disclose that the attack is really one of double form, the maniacal symptoms having been preceded by a prodromal period of depression, or an attack of drepression is followed by a state of excitement which cannot be attributed to any other cause than the fundamental cause of the melancholia. We are, therefore, constrained to believe that notwithstanding the apparent diversity of symptoms, mania and melancholia and their various combinations, as a rule, are not to be considered different morbid entities but as Kraepelin has so clearly expressed it, they are but "different manifestations of one and the same fundamental pathological process, equivalents, so to speak, like the many forms assumed by epileptic paroxysms."

The symptoms of a typical case of manic-depressive insanity are about as follows: If the attack is maniacal there is usually a short period of depression lasting for a day or two during which the patient sleeps poorly, takes less nourishment than usual, and then begins to show marked motor activity. He is busy all the time, working at many things but finishing none. Along with the motor restlessness there is mental restlessness or "flight of ideas." The patient jumps from one thought to another. He talks rapidly and goes into infinite detail as to his plans; asks many questions without waiting for answers; showing feeble attention, sluggish association of ideas, and insufficiency of perception; he builds air-castles; he is exalted, cheerful, and happy; his memory is usually good, and he has a fair mental grasp of things about him, but *judgment* is greatly impaired. If the attack is very severe the motor restlessness is extreme; the patient throws himself about violently, jumps out of bed, runs about the ward unless restrained from doing so, and often makes assaults on anyone who opposes him. Frequently while talking he hears a remark made by someone else, or the blowing of a whistle, or the ringing of a bell, and at once includes these incidents in his remarks, showing the symptom known as "distractability." These patients are happy as a rule, but if opposed are apt to become resistive and violent, striking, biting, kicking, and expectorating at those who offend them, showing "irritability" and "impulsive actions." They may laugh one minute and weep or curse the next, without any apparently deep emotional cause, and this rapid change of the emotional state is quite characteristic. When delusions occur with these patients they are usually not "*fixed*," on the contrary they change rapidly. It is difficult to gain and hold their attention on account of their excited mental and motor condition.

In the depressed form the onset is not usually as sudden as in the maniacal form, there is usually retardation of both thought and action. These patients talk but little; they move slowly and are easily fatigued. They answer questions in a slow and hesitating manner, and when asked why they do not answer more promptly they say that they cannot think of anything to say, and if they do think they find it difficult to formulate the answer in words. Emotionally they are much depressed and apprehensive, as is readily seen in their facial expression. Nothing seems right to them. Every thing has gone wrong. Delusions and hallucinations are prominent symptoms. The delusions are mostly self centered and are frequently referable to some imaginary physical infirmity. Attention is difficult to get and hold on account of the patient's preoccupation and depression. Memory, mental grasp, and orientation are usually fairly good and there is usually some insight as to their condition. The tendency in these manic-depressive cases is *toward recovery* and many of them enjoy long periods during which mental disturbance is entirely absent. These cases are to be carefully differentiated from the involution melancholias that occur at the menopause and from the senile melancholias that often attend the final breakdown of all the vital processes.

To Kraepelin we are also indebted for another term now generally used in psychiatry. It is "dementia præcox." As long ago as 1874 Kalhbaum, and later Hecker, described an adolescent insanity under the name of hebephrenia. In 1894, Kraepelin revamped Kalhbaum's and Hecker's descriptions and made a new group, including catatonia, which had previously been considered an independent affection, and gave to it the name of "dementia præcox." French and American alienists have adopted this term and to-day it occupies a prominent place in the literature of psychiatry. Dr. Adolf Meyer, until recently director of the Pathological Institute, New York City, believes that the creation of dementia præcox as a definite insanity group is the greatest advance in psychiatry in modern times.

Now, since this term is held in such high esteem it behooves us to understand what it means. The time at our disposal is too short for anything approaching a complete description, so I must content myself with a brief outline. Kraepelin observed that there were certain features common to many of the so-called terminal dements which exist from the very beginning of all cases that ultimately deteriorate. Briefly stated, these signs are the appearance of "negativism" or senseless resistance to all external influences; "stereotypy" or movements of monotonous and meaningless character, *e.g.* walking in a small circle or square, combing the hair without a comb, washing the hands without water, etc., "mannerisms" and what the German call "Willenstörung" or impaired volition, and "mutism" or refusal to speak. All of these are significant symptoms. Memory and orientation are usually good, but delusions and hallucinations are commonly present in these cases and judgment is always defective, but the existence of negativism, stereotypy, mannerisms, mutism, and inhibition of the will are the features on which an early diagnosis of dementia præcox is to be made. Dementia præcox now includes what was formerly known as hysterical insanity—the chronic manias and melancholias and nearly all of the paranoias that were once so common.

Three forms of dementia præcox are usually recognized: they are "simple dementia præcox without delirium"; "dementia præcox of the catatonic form," and "dementia præcox of the delusional form." In simple dementia præcox without delirium there is mental deterioration without delusions but with

more or less marked change in disposition. The change develops gradually and for a long time may be unnoticed. An individual previously intelligent, active, and industrious becomes indifferent and indolent. His mental field becomes more and more contracted and his stock of ideas grows steadily smaller. In the catatonic form of dementia præcox the normal will is paralyzed and automatic acts supervene. Two phases are met with, viz.: catatonic excitement and catatonic stupor. In the former state the excitement is emotionless, unaccompanied by delusions as a rule, and influenced by external impressions. Such patients yield to sudden unreasoning impulses, as the breaking of furniture, throwing objects violently across the room, calling loudly for food when a tray with the food called for is immediately before them. Such patients will walk to and fro over a limited space for hours at a time. Delusions and hallucinations are rare. In the stuporous phase of catatonia there is profound disorder of consciousness, but as a rule the patient, although apparently dead to his surroundings, notes with surprising keenness, what takes place about him. His lack of response or reaction is due entirely to a disorder of his will power. Negativism, stereotypy and pathological suggestibility are prominent features of the symptom complex, and echolalia and echopraxia are also frequently present. These stuporous patients will often lie in bed for months or even years, soiling themselves and requiring the constant care and attention of a nurse.

In dementia præcox of the delusional form the delusions are often accompanied by hallucinations and follow one another rapidly without any connection or goal idea, or any attempt on the part of the patient to explain them. In other cases the delusions are more or less systematized about some dominant idea, and to this type the term "paranoid dementia" is often applied. Further subdivision into varieties and "allied states" is also made, but the scope of this paper does not admit of their discussion here. In all of these cases the mental powers steadily deteriorate until they end in more or less complete dementia.

In conclusion permit me to make brief reference to the term "paranoia" which has been current in medical literature for more than a century, and, until less than a score of years ago was generally accepted as meaning a chronic, delusional, and incurable form of mental disorder. As recently as 1890 Krafft-Ebing of Vienna, in his text-book on insanity (page 368), wrote "The term (meaning paranoia) is applied to a chronic mental disorder occurring exclusively in tainted individuals. Its development and course are always chronic; its development is slow through months or years of incubation until its height is reached. It then remains years or decades stationary, but never ends in dementia." "Recovery I have never seen in the observation of more than a thousand cases." The influence of such an eminent alienist as Krafft-Ebing was far-reaching and in a comparatively short time his views were almost universally adopted. The term paranoia was, therefore, considered synonymous with incurability so that when the diagnosis was made there was practically no hope of recovery. During the past twelve or fifteen years, however, the opinion has steadily gained ground that Krafft-Ebing's conception of paranoia was not correct. Alienists in Europe and America began to note with surprise that some of their presumably incurable paranoiacs got well. The systematized delusions of persecution faded away; insight as to the nature of their relation with the rest of the world reappeared, and the paranoiacs resumed their places in their families and business affairs. It then began to be realized that persecutory delusional ideas, even when fairly systematized, did not always mean paranoia in the Krafft-Ebing sense, but that they were symptoms of other mental disorders which merely bear a resemblance to Krafft-Ebing's paranoia. To express this conception, Wernicke of Germany has given us the comprehensive term "paranoid states." Mendel of Berlin, and Morselli of Turin, go still further and describe a "rudimentary paranoia" in which the pathological symptoms all disappear in a few weeks and complete recovery results. Mendel also describes a typical paranoia with acute simple and acute hallucinatory forms which sometimes ends in recovery in a few weeks or months.

In our State hospitals in this country, it is true, we do not see many of the rudimentary cases of Mendel and Morselli for the reason probably that they are treated outside of institutions and often run their course to recovery without need of asylum or hospital care, but we frequently meet with Wernicke's paranoid states associated with manic depressive insanity, or melancholia or dementia præcox. In some of the manic depressive cases and melancholias, the paranoid symptoms all disappear with the general upbuilding of the patient's health and the cases end in complete recovery. Care must, therefore, always be exercised lest we lay too much stress on the existence of systematized persecutory delusions and give an unfavorable prognosis in cases which may ultimately make good recoveries.

POSTSCARLATINAL ANURIA FOR FIVE DAYS IN A BOY OF THREE AND A HALF YEARS; RECOVERY.*

By W. P. NORTHRUP, M.D.,

NEW YORK.

PROFESSOR OF PEDIATRICS, THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL.

THERE are two reasons for reporting this case: it is rare, and it was exceptionally well observed. There are a few cases on record. One case of 8 and one of 25 days anuria, with recovery, after scarlet fever, have been reported and seem to be authentic. Both were cared for by painstaking parents and servants, and watched by physicians. However, in the first case, two warm tub-baths were administered daily, by these "careful parents" (in the 8-day case) and though they were careful and though they watched with fond parental anxiety for the passage of urine, knowing full well what it would mean, they saw none pass—either in the bath or elsewhere.

I desire to give the present case its full value and therefore state frankly that the patient was the grandson of our distinguished colleague Dr. S. J. Meltzer, the son of Dr. John Auer, both known experimenters and expert observers, working in the Rockefeller Institute. Furthermore the mother, Mrs. Auer, is a medical graduate and skilled ophthalmologist. When I have added that the patient was the only son and the only grandson, I think I have sufficiently emphasized the fact that he was closely observed and that he positively passed no urine without its being noted. A trained nurse was

*Read before the Association of American Physicians, Washington, May, 1910.

also in attendance and one or both parents, night and day.

The case is rare; it is authentic. The history may be divided into three periods.

First Period of 12 days. Memorandum: Boy 3½ years old; scarlet fever, usual eruption; severe angina with pseudo-membrane on tonsils and fauces: Diphtheria antitoxin 5000 units: No *Bacilli diphtheriæ* found subsequently: the antitoxin was injected partly intramuscularly in the scapular region. Half an hour after the injection, boy is said to have had a moderate chill and become moderately cyanotic, in partial collapse. From this he rallied without serious trouble. For 3 or 4 days, beginning almost immediately after administration, he had a striking urticarial rash. It appeared in great areas over his body, appearing and disappearing. Temperature touched 102°, then 105.5° once, and 105° F. four times during this period. Pulse was 120 to 160. Urine passed was recorded daily, quality fair, quantity, 525, 525, 570, 875, 300, 50 c.c. Trace of albumin, no casts. A soft blowing murmur was noted at the apex.

The second period consists of 5 days, during which time I saw the child daily. On my first visit the urine passed up to noon was 50 c.c. Temperature was 104° F. The questions before the consultation were:

Why was the temperature so high on the tenth day?

What was the significance of the heart murmur?

What about the diminishing urine?

The abdomen was distended; the throat very red and swollen; the tongue bright red "varnished." Neither the pneumonia nor the condition of ears could explain the temperature or the rapid respiration. The throat was deep red, swollen. Urine, alkaline, contained a trace of albumin, no casts, sp. gr. 1015-1020, few blood cells, few leucocytes, enormous number of renal cells (exam. by Dr. Auer). It was thought that the throat and intestinal tract were responsible for most of the febrile reaction. A full dose of castor oil was advised. It must be remembered that the urine for half a day was still 50 c.c. The temperature fell after the castor oil to 100° and the second day touched normal. A few drops of urine were passed; slight edema of the face and feet.

Second day. No urine passed; none in the bladder.

Third day. No urine. I had had experience with suppression for 50 hours and 72 hours and had words of encouragement. In my desire to be of comfort, I confidently assured the parents and friends that the kidneys would resume their functions again, and that when they did, the first urine passed would probably be beef-tea in consistence and bloody for some days, gradually becoming more and more copious. Such is usual with scarlatinal nephritis.

Fourth day. No urine. The boy was becoming very edematous, waterlogged. He could not be lifted, so heavy was he. He flattened out on the bed immovable, eyes almost closed, hands, feet, legs swollen, skin shining, ascites. Yet he had no symptom of uremia; no nervous signs; no twitching; not dopey; no insomnia; vision clear; no headache; no vomiting; breath of normal odor; no clammy perspiration; skin natural. There was no delirium; pulse tension not increased; tranquil, not somnolent, slept naturally; temperature not above 100° F. He just thickened and flattened over the

Fifth day. No urine, general anasarca, ascites, heavily watersoaked. At this time no one could offer further prognostications. The favorable features were the absence of all nervous signs. Yet it was hoped that in some way the kidneys would resume their functions. It was argued that, the patient being a child, "there is nothing a child cannot do."

We exhausted all resources—traditional, and new. Nothing medical appeared to have the slightest effect upon the renal functions. The general impression was of some inhibition upon the action of the kidneys whereby they simply lay inactive in the bottom of the abdomen. The mental atmosphere of the household may well be imagined.

To summarize this second period: For five full days, the boy passed into absorbent cotton only a few drops of urine,—not enough to measure. He had no symptoms of uremia, became waterlogged.

Third Period. After noon of the fifth completed day or beginning of the sixth, the patient had passed 40 c.c. urine. The amounts were in drams, one, one-half, two, one, etc., passed in spurts. The next day he passed 300 c.c., beginning (at one time) with one ounce. The next days 600 c.c., 1000 c.c., 1750 c.c., 2100 c.c., etc. The first urine passed was rich in albumin, reddish, contained a large number of granular casts. It was not of the usual beef-tea-like fluid.

At this moment, the boy is entirely well, no albumin, no heart murmur, ear drum healthy. In short, he is perfectly healthy and shows no trace of his illness.

Points suggested for discussion: (1) Was there purely a toxic inhibition of the kidney functions? (2) Was there a possible swelling of the kidney within its capsule, prohibiting function, and was this in any way analogous to the urticarial swelling of the skin? Angiomatous? (3) Would anyone nowadays, in a similar case, suggest splitting the capsule surgically? In the present case our patient recovered, but would one again wait five days?

Summary.—(1) It is an authentic case of anuria of five days' duration.

(2) The case is rare, but not unique.

(3) The probable cause is toxic inhibition.

(4) Inflammation of the kidneys, as evidenced by the urine, was not severe. Recovery was prompt and complete.

(5) There were no uremic symptoms.

(6) Whether there was any relation between the excessive urticaria of the skin and the antitoxin (diphtheritic) is merely conjectural.

(7) The kidneys seemed to lie in the bottom of the abdominal cavity inactive, while the body became waterlogged.

REMARKS ON THE HISTORY OF FORENSIC MEDICINE FROM THE RENAISSANCE TO THE XIX CENTURY.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

Historians generally consider the promulgation of the criminal constitution of Charles V, otherwise termed the Caroline Constitution, as a decisive foundation of the development of legal medicine in Europe. This constitution was voted at the Diet of Ratisbonne in 1532 as a law of the Empire. Without doubt it would be an exaggeration to attribute to the Caroline Constitution a revolution or an imbed.

pulsive initiation in forsenic medicine, because, as I shall point out, relative to visits and expert work by physicians and surgeons, as well as the necessary information to be obtained from them on those questions of their art which could be used for evidence, this code simply was in conformity with the old practices observed before its promulgation in various jurisdictions, although it generalized them. It is well known that in 1507 John of Schwatzemberg, chancellor of the bishop of Bamberg, had drawn up an ordinance for this prince (which later on served as a basis for the Caroline Constitution), in which the work to be done by physicians in medicolegal practice was regulated. It should also be noted that in the articles relating to rape, abortion, infanticide, and poisoning, or dementia of the accused, absolutely nothing is said of verification or medical reports from physicians, although such reports seem indispensable in the majority of cases, but it is an undoubted fact that many years before the German judges had recourse to them.

The following are the only articles of the Caroline Constitution in which recourse to physicians or midwives is rigorously specified. I would draw particular attention to the last two, as they show a tendency to the performance of autopsies.

Art. 35.—If a girl is suspected of having been delivered of a child in secret and to have killed this child, one should in the first place ascertain if she had been seen in a very apparent condition of pregnancy, and if this pregnancy having diminished, whether or not she became pale and weak. If these kinds of signs and indications are met with and the woman is such that she may be suspected, it is proper to proceed still further and have her secretly examined in private by reliable and experienced matrons. If this examination confirms the suspicion, and she, nevertheless, will not declare the crime, she may be put to torture.

Art. 36.—When the child is killed only a short time before, the mother will not have lost her milk, so that the milk may be drawn from the breast, and if it is good and perfect, this would be a strong and evident presumption to cause her to pass through the torture. Nevertheless, since some physicians teach that occasionally from natural causes milk may occur in a girl who has never been pregnant, and if such a fact is invoked, a more ample verification must then be made by the midwives.

Art. 147.—If a person who has been struck and wounded dies at the end of a certain length of time in such a manner that it makes it doubtful whether or not the blows or wounds have been the cause of death, experienced surgeons should be consulted, who will know whether the death occurred before the blows and wounds were received, and if this is not the case they can indicate how long the person has survived after receiving them.

Art. 149.—Finally, so that as little needless work as possible may be done in the above-mentioned cases before inhumation has taken place, in the examination and appreciation of the lesions and because of the wounds, the judge, accompanied by one or several surgeons, who have already taken oath, should proceed diligently with the inspection of the corpse before burial has taken place and to take note of, and very exactly describe, all wounds, cuts, marks, or contusions which may be found, so that each one will have its own indications.

It cannot be denied that the Caroline Constitution had a very considerable influence on the development of forensic medicine. In the first place, this code regulated the legislation in all the countries of the Empire, that is to say, the larger portion of civilized Europe. Then, again, the promulgation was made during a remarkable phase in the history of the medical sciences; when the Renaissance was at its full development, at a time when anatomy, the only true foundation of modern medicine was being founded by the efforts of Ingrassius, Eustachius, Fallopius, Varolius, Arantius, and, above all, Vesalius, who, in 1543, gave to the world the first description of the human body made after nature. It should also be recalled that in Germany the great importance of experts was understood at a very early date. Consequently, the office was only confided to men having recognized morality and superior knowledge, and these alone were specially appointed experts to the courts of justice. The decisions of the experts, particularly when the case was one of a capital offence, were submitted to discussion at the universities; the Faculty would make the commentaries on all resources that the medical knowledge of the time could furnish and they published them, periodically, so to speak, having in mind a branch of instruction which had been recognized as necessary. In point of fact, the professorship of forensic medicine was created early in the seventeenth century in all the German Universities, while it was only in the year III of the Republic that legal medicine was taught in France.

In 1603 Henry IV ordered his first physician, Jean de la Rivière, to appoint a commission "in all the good cities of the Jurisdiction of the Kingdom, composed of two persons belonging to the art of medicine and surgery, possessed of the best reputation, probity and experience, to make visits and reports in justice." An exception was made for the sworn experts attached to the Chatelet; these were appointed by the king himself. Very much later, in August, 1670, the criminal ordinance of St. Germain en Laye, an appendix to the Code Louis, confirmed and regulated the already existing condition of affairs, and I will here give the articles of this ordinance which concern forensic medicine.

Title 5.—*On Reports of Physicians and Surgeons.*

Art. I.—Wounded people may be examined by physicians and surgeons, who will state their true condition; this will also be done in cases where death results and the report will be admitted at the trial.

Art. II.—The judges may order a second visit to be made by the official physicians and surgeons, who shall take oath, and after their visit they shall write out and sign the report on the spot, which will at once be transmitted to the court, and added to the documents of the prosecution.

Art. III.—We command that in all reports ordered to be made by justice that at least one of the surgeons appointed by our first physician shall be present at the place where it is made, otherwise the report will be considered *nil*.

In Title VI, Art. 23, it is stated that if any woman, before or after having been condemned to death, appears to be or declares herself pregnant, the judges shall order her to be visited by matrons appointed for the purpose, and who shall make their reports in the form prescribed for experts. If she is found pregnant, execution will be deferred until after delivery. In 1602 a regulation was issued describing the form to be given to the reports. For autopsies it ordered a delay of twenty-four hours in winter and twelve hours in summer. The report should indicate the number, direction, and depth of

the wounds, likewise their breadth, precise location, and their lethality; the expert was also instructed to state with what instrument or arms the wounds had been inflicted and whether or not the victim would remain a cripple from the effect of the wounds, or, on the other hand, how long it would take for a cure to be complete.

From a small but interesting work entitled "Doctrine des Rapports" by Nicholas de Blégny, Surgeon to Monsieur, I will quote some supplementary information relating to the organization of the medico-judiciary personnel of the seventeenth century:

"Sworn surgeons have been appointed in order to prevent the abuse which might accrue if all surgeons were allowed to make reports in Justice; because the incapacity of some and infidelity of others would be powerful obstacles to truth. . . . There are two sworn experts in every city possessing courts bishopric . . . and one in all other towns or places. They bear the title of ordinary councillor physicians to the King, or sworn surgeons. They take oath before the officers of the court; they conjointly or separately occupy themselves with reports to the exclusion of all other masters. The judges cannot receive any other report unless signed by them. They are charged with the inspection of all the surgeons of the cities in which they reside and of the cities or places belonging to their district. They may examine the candidates for the mastership in surgery and the midwives and give them their diplomas."

The reports made out by the experts were of three kinds: (1) Accusation reports, delivered upon a simple request of the parties to the litigation by any surgeon who had been sworn; (2) provisional reports, made upon the demand of the judge by the sworn surgeons of the jurisdiction in which the trial took place; (3) mixed reports which were delivered on the simple requisition of the parties to litigation by sworn surgeons alone.

Besides the above reports, experts were also obliged to make out two other types of juridical papers, namely, the "essoin" and "estimates." There were three types of essoins: (1) The ecclesiastical essoin which was an exemption of conventuel and monastic vows; (2) the political essoin, which related to the health of soldiers and those in the service of the royal houses; (3) the juridical essoin, which was required in order to postpone a trial when one of the parties could not appear on account of illness. The report of estimation was the valuation of the cost of operations and dressings when this cost was contested by the patient.

I have now reviewed the principal medicolegal ordinances promulgated in Europe during the Renaissance and the XVII century and will now examine what scientific occurrence took place relative to forensic medicine during this period. In the first place, the first work dealing with the subject appeared in 1575. The father of modern surgery, Ambroise Paré, is the author, and from this fact he should also be called the father of legal medicine. His writings on the subject are represented by a few pages which precede the twenty-seventh book of his surgical works. They represent the first steps in medicolegal science. Paré says that the young surgeon should be instructed in the art of making out a report when he shall be called upon by the courts, either for the death of the injured, resulting impotency, or the loss of some part. He points out that he should be particularly careful and alert in his prognosis because the ultimate outcome of certain wounds and injuries is very uncertain. He also says that the foremost and principal quality for the surgeon is that he shall have a pure soul, fearing God and never reporting a small wound as a large one nor *vice versa*, because the jurisconsults will be guided in their decision by the report.

From this time on works on forensic medicine were published in large number. In 1597, Baptista Condronchi, a physician of Imola, published a work entitled "Methodus testificandi, in quibusdam casidus medicis ablatis." He here studies the principal legal questions brought up in cases of disease and wounds, sudden death, poisoning, puberty, virginity, pregnancy, and labor. The work ends with a few examples of reports bearing on facts which occurred in his practice and which are most modestly signed: "I, Condronchi, the most humble of physicians and philosophers of Imola." In 1602, Fortinatus Fidelis, a physician of Saint-Phillip of Agirone, published a book entitled: "De relationibus medicorum in quibusdam ea omnia, quæ in forensibus, ac publicis causis, Medica, referre solent plenissme traduntur."

The most important and complete work of the epoch is without doubt the "Quæstiones medico-legales," published in a fragmentary way from 1621 to 1658 by the Italian physician, Paul Zacchias, physician of the States of the Church. The author received great and enthusiastic praise from both physicians and theologians of his time and the authority of this work was maintained for nearly two centuries. In this book, which bristles with erudition, is to be found a quantity of medical questions studied from the viewpoint of the Canon law, and in reality belongs more to the confessional than to the courts of justice. Conjugal duty, miracles, fastings, and other religious rites, stigmates of sorcerers, monachal claustration, in the medical aspect, find considerable space. However, all these things would naturally be treated by a physician of Innocent IV, at a time when the Canon law held a prominent place.

In France we have the treatises of Gendry of Angers, of de Blégny of Lyons, in 1684, and particularly "L'Art des Rapports," published by Devaux in 1708. The latter remained the vade-mecum of the sworn surgeon for an entire century. In 1598, Séverin Pineau, a student of Ambroise Paré, published a book entitled: "De virginatis notis," which contained the results of his researches relative to the existence of the hymen, a very much discussed question of the time. In 1611, Vincent Tagereau attacked the peculiar custom of the congress in his "Discours sur l'impuissance."

And, lastly, forensic medicine became enriched at the end of the XVIII century by a capital discovery, because in 1663 Bartholini studied hydrostatic pulmonary docimasia, which had already been foreseen by Galen, and Johan Schreyer, a physician of Silesia, applied the method for the first time in juridical matter in a case of infanticide.

Without entering into detail, I would like to indicate the character of these early works on legal medicine. If one simply goes over the index of the treatises by Fidelis and Zacchias, one will at once perceive the ensemble of the problems which presented themselves to these early medicolegal specialists in the application of medicine to Canon law, Civil law, and Criminal law. The following are the subjects which are more particularly studied from the medicolegal standpoint: The classification of

ages, sterility in the female, impotency in man, the signs of virginity, pregnancy, and labor, the duration of gestation, irregular parturitions, and the birth of monsters, hermaphrodites, obsessions, sorcery, demoniacal possession, philters, the simulation of disease or infirmities, contusions, and wounds, accidental death or death by violence, miracles, resurrections, etc. Among these questions there are some which have still remained and will continue to remain, in the decision of which the courts will always resort to medical science for information. Others have disappeared with the fall of the Canon law and the change in customs. Then again, others which owed their existence to the imperfect knowledge of the time, the love of the marvelous and superstitions, little by little fell by the wayside as the scientific mind became developed.

The Renaissance and the XVII century consequently mark the commencement of the scientific period of forensic medicine. Like all the other branches of medicine this one received a remarkable impulse, and although the latest born, it very soon occupied a very large place in the history of medicine.

As has been pointed out, Germany, from the Caroline Constitution, was the first to outline a criminal procedure and to form an excellent organization of forensic medicine. A special and competent personnel, the teaching of the subject in the universities, combined with regular and extensive observation, were all conditions which assured a remarkable development of legal medicine in this country. Beginning with Zacchias, one will find a very large number of periodical publications and general treatises in which the most interesting cases have been collected and commented upon. Among the principal works I would mention that of Welsch, which appeared in 1660, in which he considers the fatality of wounds and advises the performance of autopsies. The book is entitled, "Rationale vulnerum lethalium judicium." In 1689, Bohn treated the same subject much more deeply in a work which possesses considerable authority, entitled, "De renunciatiome velnerum."

In the XVIII century we find the "Pandectæ medicolegales," by Michel Bernhardt Valentin. It is a collection of medicolegal questions asked by the German courts during the XVII century and discussed in the universities. This example was followed by Zittmann in 1706; Alberti, in 1725; Loew, in 1725. Richter, in 1731, gave a collection of decisions rendered by the universities and the civil and ecclesiastical courts. The general treatises which hold a prominent place in medicolegal literature should also be mentioned. Teichmeyer's treatise, published at Jena in 1722, entitled: "Institutiones medicinæ legalis vel forensis in quibus praciturae materiæ civiles, criminales et consistoriales traduntur" is of great importance. Then come those of Goelicke, in 1723; Eschenbach, in 1746; F. Hoffmann, in 1746, and the classical treatise by Hebenstreit, in 1753, entitled, "Anthropologia forensis sistens medici circa rempublicam causasque dicendas officium." And lastly, the works of Daniel and Plouquet on pulmonary docimasia; of Heister, in 1727, on precocious and tardy births. The great men of medicine, van Swieten, Haller, and J. P. Franck are also associated with legal medicine of the time.

France was far from being so richly endowed in works on forensic medicine, but there were, however, some very important cases which occupied the attention of physicians and resulted in important researches. Thus, Lecat, in 1750, put forward his singular theory of spontaneous combustion, a theory which was so greatly credited in popular imagination, and which was even accepted for a certain time by scientists. Then, Lorry discussed the questions of survival.

In 1765, tardy birth was the object of very bitter discussion among Bertin, Lebas, Bouvard, Petit, and Antoine Louis. The latter in his "Lettres contre la légitimité des naissances prétendues tardives," raises his voice against the guilty indulgence of the courts who declared legitimate births occurring after twelve or even thirteen months, basing their opinion on a very old belief accepted not only by the people, but by the majority of physicians. It was also Louis, who, by his memoire read at the Academy of Surgery in 1764, contributed to rehabilitate the memory of Calas. In 1775 he was ordered to make an expert examination which saved the life of two accused persons. The circumstances are briefly as follows: On June 14, 1775, an inhabitant of Montbrison, by name, Jean Chassagneux, fell and fractured his head. This fall was accidental, but public rumor made it appear that a crime had been committed by the son and daughter-in-law of the victim. The first physician consulted concluded that the accused were guilty, but Louis was called in on the case and demonstrated beyond a doubt that the facts collected were insufficient, and that the examinations made would not allow one to pronounce judgment against the accused. Upon this report, Parliament dropped the procedure.

Louis also demonstrated juridical errors in the cases of Montdailly Syrven, and Baronnet in very important reports to the courts in which he unceasingly protested against the insufficiency of the medicolegal organization in France, also the incompetency of the experts selected by the magistrates.

We should also mention Lafosse, known by his critical examination of the Calas case, which resulted in a friendship between himself and Voltaire, and Chaussier, who, in 1783, in a memoire which has remained celebrated, shows the great importance of legal medicine and draws the attention of the courts to the inconveniences resulting from the system employed at that time. Forensic medicine was, in point of fact, arrested in its development by numerous causes which can be classified under two heads, namely, the imperfection of criminal law, and the bad organization of medicine at the time.

The principle of the necessity of a confession in order to pronounce a sentence in capital cases had been introduced a long time since with the ecclesiastic law, but it was only tutelary in appearance. In point of fact, this confession was, above all, obtained by odious means, namely, the preparatory, ordinary, and extraordinary question. And still more, the trial was conducted behind closed doors, and in many cases the accused had no lawyer for his defense. The magistrates were possessed of full power, which, if necessary, could be given to extraordinary commissions. Finally, under the empire of the criminal ordinance of 1670, the most pitiless repression was exercised to such an extent that the sentence of death was rendered in one hundred and fifteen cases in that year, this often being accompanied by torture. On the other hand, on account of the defective organization of the medical corps, forensic medicine was in the hands

of illiterate and insufficiently educated surgeons. The judges, not appreciating the importance of this science, were of the opinion that a little practical knowledge of anatomy and surgery was sufficient to make an expert. Occasionally they even made an appointment outside of the medical corps and thus, in the Calas case, the expert selected was the executioner. I would also add that the old Faculty of Medicine of Paris was far more occupied in maintaining its rights than in contributing to the progress of science, and consequently offered no course of instruction in legal medicine.

But toward the end of the XVIII century a series of occurrences of a political and social order changed the legislation and resulted in the introduction of a great many things favoring the development of forensic medicine. The abolition by Louis XVI of the preparative question, in 1773, and of torture, on May 13, 1778, was the premonitory sign of a change which would take place in criminal legislation in France, and it is well known that the Revolution precipitated the event.

In 1797 Fodéré published the first treatise on forensic medicine which had appeared in France. This book, which was at the same time both philosophical and practical, was the foundation of modern legal medicine in France, just as the work by Zacchias had been in Germany the starting point of the development of this science.

With the advent of Fodéré, forensic medicine became definitively engaged in a scientific direction, and at the same time completed and extended its domain, passing by successive phases until at the present time it comprises all the branches of the science of medicine. Thus, in the first place it was only based on anatomical knowledge, but later on chemistry entered for a large share, particularly in toxicology. The important branch of mental disease was developed by the magnificent work of Pinel, Esquirol and their successors. Later on, forensic medicine came into possession of new arms; we refer to the microscope and spectroscope, which developed the almost certain detection and the nature of spots and stains, and finally thanatology made its appearance. In 1821 Orfila contributed very greatly to the progress of toxicology by his experiments and judicious criticism, while Devergie (1798-1876), by the precision of his researches, made a great step toward certainty in the practice of forensic medicine. From 1818 to 1879 the great Tardieu was the means of causing a large number of medicolegal studies throughout the world. These have been continued and developed in Germany by Casper, Machska, Eulenberg, Liman and Kraft-Ebing, by Hoffmann of Vienna; in England by Thompson, Guy, Taylor and Christison, while prominent in the modern Italian school I would particularly recall the names of Cresshio, Tamassia, Morselli, Tamburini, Ziino and the regretted Lombroso.

871 Beacon Street.

THE HOSPITAL TREATMENT OF NERVOUS DISEASES.

By PEARCE BAILEY, M.D.,
NEW YORK.
PHYSICIAN TO THE NEUROLOGICAL INSTITUTE.

In the chairman's address before the section on nervous and mental diseases at St. Louis in June (*Journal of the Am. Med. Assn.*, June 11, 1910), a plan was given for the institutional treatment of nervous and mental diseases. If I read the article right, however, the specifications there outlined were intended to provide for cases of essentially psychiatric character, and little mention and little provision was made for diseases more plainly belonging to the nervous system. It seems to me worth while, therefore, to take this opportunity to appeal for hospital care for a class of cases which, more than any other in need of proper therapeutic management, are neglected more than any other. Every large American city has one or more dispensaries exclusively devoted to nervous diseases. These dispensaries have a bulky attendance, they are more or less equipped with apparatus for diagnosis, some of them are supplied with the simpler apparatus for treatment, and all of them are in charge of neurologists. But, once the diagnosis is made in these outdoor clinics, the proper disposal of the sick man is a matter of difficulty. The patients are too permanently or too indefinitely ill to be welcome in the wards of a general hospital; and even when some few of them gain entrance by some means or other, they get little benefit, as there are no general hospitals equipped either in personnel or appliances to properly treat nervous diseases. The dispensary physician, therefore, is limited in his therapeutic efforts to such advice as he can give in brief and frequently interrupted interviews, to such luck as may follow his choice of pharmacological remedies and the recommendation of such physical treatment as may be obtained in hydrotherapeutic establishments, electrical establishments, etc., over which he has neither supervision nor control. He cannot enforce any of his recommendations and fails utterly to obtain a close knowledge of his patient. He cannot place him in a hospital ward, as few, if any, of the dispensaries for nervous diseases in this country have hospital wards available in which patients who are acutely ill or who require observation for diagnosis can be under the continuous observation of neurologists. But the fact daily becomes plainer that until such provision for the treatment of this large class of patients is made, neurological therapeutics must remain far below the standard of its possibilities and prognosis in nervous diseases must continue to be very much more gloomy than it ought to be.

The object of hospital treatment for nervous diseases, as for others, is curative, ameliorative, and diagnostic. The curative treatment when operative consists of all neurological operations. This means not only that the neurologist is a preoperative adviser, but that this neurological care is not interrupted. The surgical results that may be obtained in a neurological hospital are exemplified in the highest degree in the Hospital for Paralyzed and Epileptic in London. There, with no surgical service, Sir Victor Horsley, operating on the cases submitted to him for operation by the hospital physician, has won his fame as the first and greatest surgeon of the nervous system. The operator in a neurological hospital has fewer chances of error, as the cases given him have had the benefit of more than one opinion, and one or more neurologists are present at the operation, to advise at every vital stage. The patient, also, after the operation, remains under neurological supervision so that he obtains the best after-treatment in the way of apparatus, mechanotherapy, massage, electricity, etc., upon which the success of so many neurological operations depend.

The nonoperative curative purposes of hospital

treatment embrace the reception of all the severer forms of syphilis of the central nervous system where superintended treatment is vital, and such acute diseases as meningitis and other infections and chorea, exophthalmic goiter, and certain epilepsies. Nutritional diseases such as gout, rheumatism, and especially diabetes, should be treated in hospitals for nervous diseases or at least in hospitals where dietetics and special equipments for physical treatments are highly developed. The latter disease is, in the majority of cases, of neurotic origin, and is accompanied by a vast variety of nervous and mental symptoms, its nutritional characteristics being only a small part of the total picture. In the early stages of diabetes, the determination of the patient's tolerance for carbohydrates is imperative. For this the patient must be under strict surveillance and the quality and quantity of food accurately known. This can only be accomplished in a specially equipped hospital. It is probably due to the fact that hospitals are not arranged as to their dietaries to satisfy both the needs and cravings of diabetics that so many of this class of sufferers get their education in foreign cures and from foreign physicians.

The whole class of neuroses and psychoses which are dependent upon fatigue, exhaustion, malnutrition, toxemia, and unhygienic home surroundings are generally benefited and may be promptly cured by special hospital treatment. Treated in the dispensary, such cases drag on for months and years. Patients of this kind are made worse rather than better in general hospitals where the staff is too busy with pressing tragedy to learn their needs or provide for them. Hospital treatment is necessary for many cases in which cure is impossible but in which, under proper circumstances, amelioration can be effected. This applies to the whole class of degenerative organic diseases in which, in addition to the incurable lesions, there are other circumstances which impair the patient's general health and which can be improved.

But perhaps the most important argument for the existence of a neurological hospital is for the purpose of diagnosis. Possibly 50 per cent. of the cases which present themselves at an out-patient department for nervous diseases can be correctly diagnosticated in a single interview. The others require not only repeated examinations but the sounding of personality and the exploiting of weird symptomatic trends which only come with prolonged personal contact. For such, the provision in America is most inadequate.

The need of observation for diagnosis has so long been recognized in every other branch of medicine that it is extraordinary that up to the present time no opportunities for continuous observation and for reflection have been given those who occupy themselves with the most complex diseases of all. It is only by continuous personal observation and by the reports of properly trained assistants and attendants that the physician can estimate as to the severity of pain, the character of convulsions, the reason of insomnia, the degree of disability, the condition of the digestive apparatus and the general make-up of the patient. It is psychoanalysis reduced to a practical basis. For whatever may be the value of the Freud method of psychoanalysis, it compares in no way in general usefulness with a week or two of personal observation of the patient.

With the ideas just set forth, a few of us in December, 1909, caused to be opened in New York City a hospital for nervous diseases. We had secured the backing of a strong board of trustees who had become sufficiently interested by our arguments to give the institution a trial. The hospital was equipped with every appliance for the treatment of nervous diseases likely to be efficacious, was supplied with competent nurses, with several salaried assistants, and with a little army of masseurs, mechanogymnasts, electrotherapeutists, etc.

The dispensary operated in connection with the hospital is open six days a week and suitable patients are received in the wards, which contain thirty-five beds. Ward rates are $15 a week, to include massage, electricity, Zander treatments, and all the patients may require. These rates are lowered in suitable cases, and about half the cases are treated free of all charge. By paying slightly more, patients may be in semi-private wards and many cases requiring isolation are placed in semi-private wards at ward rates or free. There are also private rooms which help in maintenance. In these latter only are physician's fees charged.

Great benefit has accrued to all connected with the institution in a professional capacity. The assistants, both those beginning their neurological career, and those finally perfecting themselves for practising neurology, have the advantage of a large clinical experience and of close observation of patients, especially with regard to the effects of treatment. Nurses have become familiar with the special demands of nervous people, and on leaving have gone forth better equipped not only as special nurses but as general nurses. It is also confidently believed that a center of neurological activity such as this hospital is striving to be will have no little influence in the education of men who, after completing their course in it, either as assistants or students, will go out all over the country as competent practitioners of neurology and with the enthusiasm to start similar institutions elsewhere. But the feature which this paper desires specially to emphasize is that of therapeutics. All the chief medical officers in the institute had been for many years in charge of large metropolitan clinics, had held professorships, had been consulting neurologists in various hospitals and all had been unable, prior to the opening of this institution, to get satisfactory results from the various services and had become very pessimistic as to neurological therapeutics among the poorer classes.

We hoped in the establishment of this hospital to raise therapeutic standards, but none of us believed that we could get the results which have come from the routine established and from the regular and superintended use of the various therapeutic appliances.

The class of cases which have had the greatest success has been that in which nervous symptoms were due largely to nutritional disorders. Some patients have been men, but more frequently they are women suffering from fatigue, insomnia, dyspeptic disturbances, marked changes in the blood, and a ruffled mental state. Such cases benefit little, if at all, by dispensary treatment. Among the wealthy classes, the patient is sent to out commercial sanatoria or to some of the health resorts of Europe. As far as I know, the Neurological Institute is the only institution in the country equipped to care for the semi-invalid, free or at less than remunerative rates. We have found, however, that such patients, after they have undergone a two or three weeks' treatment of rest, hydrotherapy, en-

forced regularity as to the bowels, a carefully selected diet, with sometimes medical remedies, and the daily counsel of physicians, improve very rapidly. Over and over again, we have found that two or three weeks of this treatment would enable the patient to resume work much stronger and much more able to stand the strain; and the knowledge gained in the Institute as to the conduct of life and the relative value of things furnished him an important asset to draw on in future times of need. Such patients are entirely unsuitable for the treatment given in general hospitals. Without minute supervision, they either drag out a miserable existence keeping at work, or are finally forced to give up work. This class of cases furnishes the most potent argument for the establishment of neurological hospitals in every large city.

A neurological hospital is also an ideal place for the treatment of cerebral arteriosclerosis. The fluctuations of this disease are so rapid, the power of recovery and re-establishment is so great that, oftentimes, a patient even when on the verge of apoplexy who is made to rest and follow a strict routine, often puts off the evil day and gains a marked improvement in all functional symptoms. In this disease we have used the high-frequency currents with success.

In chorea, also, we have found that under the quiet and routine of hospital care the spasmodic movements cease and the child returns to normal much more quickly than when treated in the dispensary.

We have also had very good success in cases of delirium, whether of toxic or of exhaustive character. Such patients as we have treated have been too delirious and delirious for too long a time to permit them to be retained in general hospitals. Had they not come to us they would have been committed to asylums.

In many of the limited cases of mental diseases, therefore, a neurological hospital may prevent the patient undergoing the stigma which is ever inseparable from commitment.

Our experience has convinced us, however, that no cases of mental disease which require restraint should be treated in a neurological hospital. This applies particularly to cases of pronounced melancholia, mania, and to such persons as are controlled by active delusions. The reason for this is that the actively insane have a bad effect on the patients, and proper care of them requires an equipment and personnel of a different character.

The chronic degenerative diseases of the nervous system of which a great many have been admitted to our wards have left us with perhaps no improvement as far as the organic lesions are concerned, but even in them some benefit has accrued. In tabes, with high degree of hypotonia and ataxia, the systematic movements as devised by Fraenkel are the only means by which the patient can regain the power of walking. As many of these patients are practically bedridden, it is impossible for them to go to any class for instruction, and as manifestly impossible for them to pay for an instructor to come to them. A number of such bedridden patients have been greatly benefited by the systematic application of the Fraenkel movements given in their beds in the hospital, and one patient in particular, who had been confined to his bed for a year, was able to walk out of the hospital after three months' stay.

Even in the organic cases in which no material benefit of any kind has accrued it has seemed that the patients were better satisfied, were more philosophical from their stay in the neurological wards. They saw that some one, at least, had an interest in them and understood them.

CONSTIPATION AND TOXEMIA.

By J. GEORGE SAUER, M.D.,

NEW YORK,

FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

The symptom constipation with the sequel toxemia is being written with more and more frequency on the history card of each succeeding generation of patients as they come before the physician in his general practice. Cure resulting from his treatment is the exception. Still, its continuance is usually the progenitor of many avoidable consequences which first distress and then shorten life. We do not, of course, know all that we should properly know about the many etiologies and the many poisonous metabolic products that we incriminate in these morbid states known as constipation and toxemia; but happily the day is now about past when these conditions are treated experimentally, and one method is tried after the other until that suited to the individual is discovered. The light of modern advancement directs our earliest efforts to its elimination, or, at least, to its tolerance, by precluding absorption of toxins, by rendering the pabulum an unfavorable media, for the cultivation of certain harmful bacteria.

Thus the systemic pathogenesis of these conditions leads us first to a consideration and study of the pabulum as a factor of its etiology and of its continuance as it passes from the teeth to the anus, and of its evolution from food to feces. We now know the pabulum to have been sterile at birth, and we also know that soon afterward it became infected with the *Bacillus lactis*, which thereafter took up its permanent abode in the small intestine, and that later became infected with the *Bacillus coli*, which elected to reside thereafter in the colon, or large intestine. We know that these, together with the *Bacillus bifidus*, constitute the normal intestinal flora, are indigenous, and exist in large numbers, physiologically respecting the boundary line of their own domain; but pathologically contending among themselves and with others that are foreign; the harmful ones growing and multiplying at the expense of the beneficent ones and at the expense of their host, whose vital tissues they then invade, producing quantities of indol and of other deadly poisons and toxemia, taxing the full capacity of his phagocytes, and the full ability of his liver and kidneys. The *Bacillus acidi lactici* does not produce indol, takes only an antagonistic part in the process of putrefaction, and multiplies and propagates at the expense of the carbohydrates; has a wholesome destructive action on milk. This desirable bacillus, which is so harmless to the human economy, finds its chief vehicle of introduction for good, and takes up its abode in the small intestine, where it prevents abnormal putrefaction of such proteids which, through faulty digestion, have escaped the action of the digestive juices, and found their way into the intestine.

Metchnikoff of Paris has elaborated and popularized, and has urged that the coming of senility may be postponed by the prevention of putrefaction in the intestine, and that this may be accomplished by the constant use of milk, soured by and containing

live lactic acid bacilli. He contends that other injurious bacterial changes in the alimentary canal can be avoided by encouraging the growth of the beneficent lactic acid bacilli therein, which will preclude the development of the injurious bacilli of putrefaction. Whether this is bacteriolytic (an anerobic and aerobic warfare) or chemic (through the development of the lactic acid in the media) is still a matter of speculation; but the fact still remains that the periodic numerical reinforcement to the ranks of the lactic bacilli by the drinking of soured milk has a salutary and beneficent influence on the economy, as is evidenced by the odorless, free, nonirritant stools, the disappearance of indican from the urine, and the cessation of the physical symptoms of toxemia. The idea of employing the results of bacterial activity to counteract putridity in the intestine is by no means new, and as presumptive evidence of the inherent probability of this proposition Metchnikoff cites the unusually long life of the Bulgarian who makes sour milk and its many modifications a large part of his daily dietary.

Metchnikoff proposed the cultivation of this bacillus in milk which has been sterilized to produce sour milk containing a pure strain of active lactic acid bacilli, and which will at the same time be free from any of the injurious bacilli of putrefaction. It is believed that this as a constant article of food will prevent the growth in the alimentary canal of the bacteria which cause putrefaction, and abnormal fermentation; that consequently there will be no toxic substances to be absorbed. Indican, which denotes an abnormal transmutation of proteids brought about by the colon bacillus in the intestinal tract, can be inhibited by the *Bacillus acidi lactici;* thus indican will be absent from the circulation, and the tissues and the organs of the body will be relieved from the destructive irritation caused by the absorption of those toxic products of bacterial growth, and as a result of this, and the changes incident to it, old age and death may be postponed.

Gaillord encourages the proliferation of the amylolytic microbes, which are useful, at the expense of the proteolytic organisms, which are harmful. As soon as the digestion has been regulated in this way defecation occurs with regularity, and without any other treatment. He cites many patients treated in this manner, with extraordinarily favorable results.

The primary and natural therapeutic remedy, therefore, points to the immediate restriction of the proteids as the offending factor; and this probably accounts for the success of this method of treatment of the constipation. The pathogenesis of the intestinal bacteria may thus, then, be divided into that due to its action within the body, and that due to its action within the intestines, the former of which is frequently that of primary constipation and toxemia, cerebral, hepatic, and renal congestion, and the latter secondary visceral ptosis, and cardiovascular disease, from the long-continued high pressure which it causes.

It has been said that any life known may be enjoyed by the subject according to his diet: The short life of him who digs his grave with his knife and fork, or the long life of the vegetarian, who has been in daily evidence since the day of St. Anthony, who reached the ripe old age of 105 years on the simple diet of bread and water, or of the Spartan who dined but once per day, or of the hardy little Jap, who, on a diet of rice, whipped the big, meat-eating Russian; or of Fletcher, who saved his life by learning how to chew his food. The principal contentions of the present day, really, are the false conceptions arising from the teachings of the nutritive values of food, the inbred provident tendencies to store up for future bodily emergencies and the modern educated palate, which, if it had a conscience, would go mad with remorse over the physical crimes of its instigation; thus, in this connection, it may be well to state that it is not what we eat, but what we need, digest, and assimilate that has a true food value. The undigested proteid in the intestine presents the ideal media for the propagation of the harmful bacillus at the expense of the lactic acid bacillus, and the formation of toxins and toxemia.

The average individual eats too much, frequently he is trying to combine the pastimes of the epicure with the habits of the recluse. One fact should be kept continually in mind, and that is that the overplus of proteid indigestion—that which is beyond the ability of the stomach to digest—is that which furnishes the culture media in the intestine for the bacteria of putrefaction, and that which is beyond the actual need of the nutrition of the body, even though stored up as pathological undermetabolized fat, is deposited as a contributory revenue for future gout and innumerable other distempers and pains.

Kohnstamm believes that there is some substance among the proteid products which fails of digestion to peptone, and has a direct inhibiting effect upon the peristalsis; or, it may possibly act indirectly by checking the secretion of the intestinal walls, thus rendering the contents of the intestine dry and less susceptible to the peristaltic action. He does not admit that man is truly omniverous, and thus incompetent to digest those large quantities of meat, eggs, and other protei'ds that the modern palate usually craves. Mangelsdorf calls attention to the fact that the condition of the stomach usually parallels that of the intestines; atony of the one usually means atony of the other, and the determination of the outlines of the stomach is usually thus an index of the condition of the intestinal musculature. Admitting the above, I would like the privilege of adding another link on either end by saying that the condition of the mouth is frequently an index to that of the stomach, and that the condition of the anus is frequently an index to the condition of the colon; and now another link in the middle, by saying that the condition of the whole alimentary canal is an index to the condition of the liver, and that this important gateway is seriously overtaxed by the gastronomical crimes of the modern palate; that the two pints of bile which are daily poured into the intestine are frequently incompetent to metabolize its putrefying contents so that its portal return is free from the bacteria which provoke the kidney beyond its ability to excrete. This spells toxemia and constipation, and if I were asked to elect the least important fatcor in the etiology of these pathologies I would not elect the mouth, for I believe that the septic stumps therein contained must often be an important etiological factor in the infection of an otherwise sterile pabulum.

Now, considering the birthright of every intestine to a normal pabulum, the regular reception of which seems to be intended for the normal excitation of the intestinal muscularis in its lifework of peristalsis, we may now ask: What are the conditions which render possible, therein, the develop-

ment of constipation, the microbe of infection, and the resulting toxemia? What are the conditions which may inhibit these pathologies? This naturally brings us to a consideration of the putrefaction-resisting values of the proteids which are pathologically considered to be the putrefiable toxin-forming factors of the toxemia which usually accompanies the constipation. Not only is the proteid of the food the one of least bacterial resistance, but it often, also, is the vehicle or medium through which the injurious bacteria are carried and propagated directly through the intestines into the circulation, and then, on the other hand, not only have the hydrocarbons and the fats the highest bacterial resistance, at least in so far as it concerns the injurious bacteria, an equal or even a higher caloric value, but they form, also, the most desirable and most easily eliminated pabulum, and they should, therefore, receive the first consideration in the dietetic treatment of those otherwise irremediable atonic conditions of obstipating constipation for which we usually resort to mechanical measures, and which at times menace life through their disposition to infection of the retained pabulum and the consequent toxemia which follows. That it is not the constipation *per se* and alone that is the whole factor in the accompanying toxemia is evident, for Bouchard cites a case of forty-day retention of dry nontoxic feces without serious sequel, and similar cases of weekly retention are not at all rare, and it is further proven by the relief that comes from the administration of the cathartic many times before the bowels move or even show a disposition to move, nor does this relief come alone from the action of the cathartic on the liver, for the frequent and prompt relief comes before the defecation, as well through the injection of a copious enema of water; but this, in my experience, cannot be said to follow the peristalsis that is mechanically set up by the dry wool tamponade of the rectum, since many times the symptoms of the intoxication continue even after the defecation. Therefore, I consider the assumption safe that the preevacuation relief is the result of the reversal of the tide of osmosis toward rather than away from the intestine. In other words, the physical law of osmosis tends to equalize the liquids on either side of the membrane which is separating them, and in the present instance, before the equalization takes place, so that the tide can reverse, the bowels move, and the relief is, for the time being, at least, complete.

The symptomatology of constipation in different individuals seems to bear a surprisingly small relation to the pabulum quantity *per se;* but a marked relation to its quality *per se*. One hour's retention of an infected pabulum will produce a greater symptomatological sequence of injury than will a day's retention of the uninfected pabulum. That this is a fact is evident in every practitioner's experience, and it is probably this fact which makes the obesophobic patient, which assures the success and raises the par value of the stock of the many laxative mineral-water concerns which thrive throughout the land. One of these advertises: "A movement of the bowels is an asset in the ledger of health." Few notice that they have left out the words "normal movement," and few are aware that this "asset," from the continual hurry of the partly digested proteid pabulum into the domain of the colon bacilli, this sweeping out of the lactic bacillary defenses before it, are the first factors in the establishment of a chronic toxemia which does many times as much harm as the simple constipation. It is in just these cases, in particular, that we get such excellent results in the reestablishment of the lactic bacillary element of the normal intestinal flora through the continued administration of the sour milk. It is the toxemia, and not the constipation *per se* that does the harm, and if the theory of Kohnstamm is right, then the toxemia may well be the etiology of the constipation, and the relief of the one means the relief of the other, and this is best accomplished and maintained by the continued reinforcement of the lactic bacilli which preclude the spread of the colon bacilli, and this can be further inhibited by the cellular hydrocarbon dietary which favors the proliferation of the lactic bacilli.

That the suggestions for treatment are far from complete, and still crude, the writer is well aware; but that it is one of the few avenues to real prophylaxis, a therapeutic measure that does not rob Peter to pay Paul, one that will preclude much of the painful, serious and life-shortening pathology resulting therefrom is evident.

105 West One Hundred and Thirty-sixth Street.

ABSCESS IN THE FRONTAL LOBE OF THE BRAIN AFTER CHRONIC FRONTAL SINUSITIS; ERYSIPELAS IN CONJUNCTION WITH ACUTE MASTOIDITIS.

By ALFRED WIENER, M.D.,

NEW YORK.

In the two cases reported below some observations were made which I believe may be of sufficient interest to warrant their report.

W. H., 28 years of age, entered my service in the hospital, complaining of a persistent headache over the right frontal region. He is single, a painter by occupation, indulges moderately in alcohol and tobacco, and gives a negative history in regard to syphilis and tuberculosis. Never suffered from rheumatism or gout. With the exception of measles, does not remember ever having been ill. About four years ago suffered from what was evidently an empyema of the frontal sinus on the right side, which necessitated, according to the patient's description, an external operation. A year later a second operation was performed. Since that time, in spite of the fact that he has suffered from recurrent attacks of excruciating headache, radiating from the region of the right frontal sinus over the entire head, he has repeatedly refused to have anything done. At no time has there been any vertigo or vomiting. There has been a periodic discharge of pus from a fistula which exists at the lower and inner portion of a depression located in the region of the right frontal sinus. Whenever this take place he is free from headache for a short time. The patient is a robust and healthy looking individual. An examination of the nose reveals practically nothing. An attempt to probe the frontonasal duct is unsuccessful.

There is no tumefaction existing either over the inferior or middle turbinated bones, nor the slightest evidence of any polypoid degeneration within the right nostril. It is free from all secretion. Externally one notices a deep depression with a rectangular scar, so placed that it prevents the patient from closing his lids, the upper lid being drawn up in a notched-like fashion just about the junction of the middle with the inner third of the brow.

Here is present a fistulous opening, covered by a scab, which when removed allows a drop of pus to escape. Upon probing this fistula one comes directly down upon bare bone. The patient of late has become rather forgetful, and at times very irritable. His vision is perfect, and the fundus in both eyes shows nothing abnormal. Heart, lungs, and kidneys are negative. A blood examination shows a leucocytosis with a differential count of 72. There is a slight rise of temperature in the evening amounting to 100°. There is distinct tenderness to percussion and pressure over the entire frontal region on the right side, especially so over the upper and inner portion of the brow.

Judging from the symptoms present, and what the patient had experienced since he had undergone two operations, both having been performed by competent men, I felt quite confident that I would have to seek for the cause of these headaches within the cranial cavity. The presence of tenderness in the frontonasal region, the periodic discharges of pus attended by relief for a short time from these headaches, the persistence of the headaches in spite of the fact that the frontal sinus had been undoubtedly thoroughly eradicated, the noticeable forgetfulness and irritability of the patient made me suspicious of the fact that these symptoms were due to a brain abscess. An operation was advised, but refused. Two weeks later the patient was found in a semistuporous state, passing from one convulsion into another. They were not of the Jacksonian type, but general. This I was able to observe personally, witnessing three attacks.

There was no doubt now about the character of the lesion. This patient was suffering from a brain abscess, probably within the frontal lobe. The convulsions were undoubtedly brought about by the collateral edema.

Under chloroform anasthesia the entire region of the frontal sinus was exposed. It was found to have been completely eradicated. On the upper and inner portion of the posterior wall there was noticed a small, black spot, about the size of a shoe button. In probing this gently my probe found its way into a cavity about three and a half inches in depth. On withdrawing it about a half teaspoonful of pus escaped under pressure. The incision in the scalp was extended up over the frontal bone, the scalp elevated and retracted, then, with rongeur and chisels, an area was laid bare about the size of the palm of one's hand. In a region about the size of a twenty-five cent piece the dura was found discolored and partially covered with granulations. These were scraped away. Instead of making a flap in the dura a crucial incision was made, the object being not to disturb the adhesions which existed between the dura and pia. The crucial incision brought me directly into the abscess cavity. The pus was allowed to flow out freely and carefully sponged until the entire cavity appeared to be clean. One could now gain some idea of the size of this abscess. I should say that it measured about the size of a small child's fist. It contained about four ounces of pus, in a semifluid state. The sponging was done with flexible applicators wrapped with absorbent cotton. When we had completely cleansed the cavity it was wiped with 98 per cent. alcohol. Before this was done I had convinced myself that the abscess was encapsulated. Instead of putting in a drainage tube, the entire cavity was packed gently and not too firmly with one-half inch selvaged edge 5 per cent. iodoform gauze. A loose dressing of gauze was placed over this, and a bandage applied.

The patient was placed in bed with the upper portion raised. His head was flexed with a slightly downward bend toward the right side. This position we hoped would favor drainage. It certainly did act so in a most admirable manner, as the dressings when removed constantly demonstrated.

On the following day the patient felt perfectly comfortable, and the outside dressings were changed. On the third day the internal packing was removed and scarcely any secretion was found in the cavity. It was allowed to fill up with granulation tissue, which it did most readily, and after seven weeks the cavity was closed. It is over one year since the patient was discharged as cured. Since that time he has had no more excruciating headaches, nor has he been conscious of any pain within this area. I have purposely waited one year before reporting this case, as I wished to assure myself that there would be no recurrence of the original trouble. He is actively engaged at his former occupation as a painter, and appears perfectly well.

Miss E. C., 45 years of age, was admitted to the hospital on the 24th of November, 1909. She was suffering from excruciating pain in her left ear. In addition, there was some tumefaction in front of and below the lobule of the same ear, with extreme sensitiveness to pressure. The patient told us that she had had several seizures of this nature, and that they always culminated in attacks of erysipelas. In none of the previous attacks, however, was the pain in the ear so excruciating.

On examination the patient showed herself to be of a robust constitution. The temperature per rectum was 102°, with a pulse rate of 96, and respirations 28. Lungs, heart, and kidneys were normal. The tumefaction in front of the ear occupied an area representing the region of the parotid gland. The skin over this area showed not the slightest evidence of an erysipelas or even an erythema. It was extremely sensitive to the touch, but did not pit on pressure. Not the slightest pain, tenderness, or edema was present over the mastoid process. The external auditory meatus was normal, but the tympanic membrane was reddened and bulging. Its landmarks were no longer distinctly recognizable. Hearing was reduced to conversation at about ten feet. While the external picture did make us suspicious of an infectious parotitis, there was no doubt about the condition existing within the middle ear, viz., an acute otitis media.

A paracentesis was advised, accepted, and performed under anesthesia. A serosanguilent fluid escaped, but no pus. On the second day the temperature arose to 103°. In spite of the free discharge, the pain was still very severe. On the third day the temperature arose to 105°, and at the same time all the evidence of a florid erysipelas made itself apparent. It occupied an area represented by the parotid region in front of the ear, about a hand's breadth below and behind the ear, directly over the mastoid process. There was now a free discharge of pus from the ear, and the pain in this region began to subside. The erysipelas spread over the face, neck, and chest, and into the scalp, with some tenderness, very superficial in character, over the mastoid bone. The temperature began to drop, and on the sixth day had reached 100°. The patient expressed herself as decidedly better.

On the evening of the sixth day she complained of feeling chilly, and the temperature arose to 104°. Toward morning there was marked tenderness and edema over the mastoid bone, with a very noticeable decrease in the amount of discharge from the middle ear. A blood count showed leucocytosis and a differential of 84. In spite of the fact that we were dealing with a rather treacherous condition, an acute mastoiditis in the presence of an erysipelas, we decided to open the mastoid in order to avoid, if possible, the more serious complications. We believed this to be the only rational procedure under the circumstances. The mastoid was opened and sufficient was found to warrant the procedure. On the following day the temperature dropped to subnormal, 97.3°, and in the evening arose to 104.2°. This rise during the first twenty-four hours did not occasion any alarm, as the patient did not appear to be disturbed thereby. Her general condition was good, and she felt most comfortable. Within forty-eight hours the temperature dropped to 99°, and ranged between 99° and 100° for two weeks thereafter. After six weeks the wound had closed and the patient had entirely recovered.

Remarks.—The case is of interest on account of the presence of a mastoiditis during an attack of erysipelas. An operation is urgently demanded. In spite of the fact that such an operation was done within the erysipelatous area, not the slightest disturbance in the way of any serious complication occurred. We are all of us aware of what a treacherous complication erysipelas is in the presence of a wound; how one serious complication after another will attend such an infection. I must confess, therefore, that I was rather surprised at what I believe to have been rather an unusual outcome in this case. The result goes to show that the idea of an erysipelas exerting a curative effect upon some wounds, as acknowledged by some authors, is not altogether wrong. Let us bear this fact in mind.

THE LODGE PRACTICE EVIL OF THE LOWER EAST SIDE.

By MORRIS JOSEPH CLURMAN, A.B., M.D.,

NEW YORK CITY.

Human progress in all endeavors has always had obstacles to be encountered and overcome. And it is a healthy fact that the medical world has not been exempt in this respect. But in the medical sphere, as well as in other spheres, optimism alone, without any other substantial aid, is not sufficient to root out and ameliorate existing evils. Aside from the great and knotty problems followers of Hippocrates have in common all over the world—including medical, social and, of late years, even political questions—there exist various local influences and tendencies in every medical community.

The vast city of New York with its labyrinth of manifold activities is not a fortunate exception to this state of affairs. Among the local medical community, especially of the lower East Side, there has sprung up of late years an evil so virile, so powerful, and so destructive toward medical ideals, that in time only a mythical Perseus will have to spring forth to destroy this Gorgon Medusa, if concerted action on the part of the East Side medical profession is not taken to check it now.

This alarming evil is nothing more nor less than the existing state of East Side lodge practice with its concomitant train of manifold degradations to the local medical fraternity. At the present time there are in existence downtown somewhere between 1,500 and 2,000 lodges, societies and benevolent associations founded mainly by the poorer class of workingmen for a double purpose; namely, social intercourse and mutual aid or benevolence. An iron-bound practice or custom has arisen for each society to elect some physician to take care of the health of the society members—for a consideration. What this consideration amounts to, we shall see later.

Stated thus baldly such a condition of affairs would seem to be reasonable, practical, and eminently satisfactory. But let us investigate more closely and see what the results of such an arrangement have been. Twenty years ago, when lodge-practice was in its infancy, societies would send humble delegates to some physician and ask him to accept the office of lodge doctor for a fair and reasonable consideration. In most cases the physician thus approached would think twice before entering into such an agreement, since, very naturally, routine family practice with its direct returns for every call seemed more remunerative than cheap contract practice. However, young and ambitious medical tyros naturally sought some means of getting patients to come to them, and this seemed an easy way to help make both ends meet and also to obtain what seemed to be a legitimate and ethical way of advertising one's self.

'Tis true that for some years all physicians who undertook such lodge practice found in it a wonderful stepping-stone towards obtaining a medical reputation. The lodge doctor found that he came in contact at the sick bed with a large class of patients who would not have patronized him in any other way. In time, however, the lodge physician, after establishing a reputation as a busy practitioner—and, perhaps, as a good one—became more or less independent. He discovered that it now paid him to disentangle himself from the onerous duties of a lodge doctor and once more resume straightforward family practice. What with the advertisement he had received, the numerous families who had employed him in the capacity of lodge doctor and the normal growth of his regular practice, he now found that financial affairs went smilingly with him even after giving up these societies. Very naturally such shining examples of medical success and pseudoprominence came to be regarded with envy by others of the East Side profession, and more especially those of the younger element.

Hand-in-hand with the increasing number of physicians on the East Side, a keen competition now arose among them to be elected as lodge physician in as many societies as possible. Many sought these positions, and it seemed that another Eldorado had been discovered, or a new gold mine had been unearthed.

But now the quilt had been reversed. It was the doctors who sought after the societies and not *vice versa* as formerly. The societies found that, inasmuch as physicians were so anxious to be their lodge doctors, they could well afford to discriminate and choose from the numerous candidates.

At first the chief qualifications for a physician who wished to be a lodge doctor were his medical skill and knowledge. But as laymen, especially those of the lower strata of working men, are not the best judges of the professional merits of a physician, it was not long before the physician with

the best business instincts "crawled and intruded" into the occupancy of these positions. The physician who knew how to ingratiate himself into the good will of some of the individual leaders or more active members of these societies was almost invariably elected. At first he simply had to be "a good fellow" with them to become the holder of the coveted positions. In time even that wasn't enough. He had to hold out more inducements. And these inducements naturally varied with the caliber of the men with whom he was dealing. Sometimes the judicious distribution of a few "shekels" among the most influential of the society leaders brought the physician the necessary votes to elect him. Sometimes it was the unwritten promise of a bounteous "blow-out" to the members if he were elected. Or again the physician would pledge himself to make free calls to all the members regardless of their place of residence, whether it happened to be far uptown or in remote sections of Brooklyn. In this manner it often happened that a worthy medical candidate would be defeated by his more Philistinic colleague. It is easy to see what a deplorable state of affairs such an unequal competition naturally and inevitably has brought about.

At the present day it is no longer a question of the physician's merit and professional ability as to whether or not he will be chosen as society doctor. Indeed it has come to be a matter of an adroit art to obtain societies; and the physician most skilfull in this art is rewarded with the bone of contention. To be proficient in this art, however, means to overstep the borderland of medical ethics and very often it means straying far beyond this borderland.

What a degrading spectacle it is to see three or four medical men at one of these society elections. Each candidate comes fully prepared with printed ballots bearing his name which he distributes among the lodge members. While the vote is going on and the ballots are being counted these physicians sit like culprits and await the result of the election. It is difficult to say who should feel more chagrined after the count is over; the lucky (?) winner or the defeated candidates. The latter have been weighed in the balance, judged, and found wanting by these poor misguided workingmen. What a farcical application of the law of "the survival of the fittest." It is not hard to see or understand why the natural respect due to the professional man from the East Side laymen has gradually become undermined and well-nigh extinct. How can the proper respect be fostered by medical men who descend to the practice of selling their art as hucksters dispose of their cheap wares?

Let us cite an actual instance showing how far this lack of respect has gone. A certain East Side lodge doctor gets a hurry call about 8 A. M. to one of his lodge families. After some delay he hastens to the house and climbs up five flights of stairs to the family in question. When he arrives he is greeted by the housewife with a severe scolding because of his tardiness. In some alarm he inquires if he has come too late. He learns that he has come too late—that is, too late to allow the youngest child to attend school. It seems that it was the opening day of school and the mother had called the physician to make out a vaccination certificate for her little daughter so that she could be in time for school with the proper credentials. Small wonder that the physician's services are held so lightly when it is proffered at such cheap and degrading terms.

To-day there is scarcely an East Side workingman who is not a member of some association which has a physician to take charge of its members. Let us see what are the average rates of remuneration for the lodge doctor. With very few exceptions the market price "per head" is as follows: One dollar a year for each unmarried member and three dollars a year for every married member including his family. And let us not forget that the East Side workingman when married does not believe in race suicide. For these terms he is supposed to make as many professional visits in time of sickness as he is called upon to do. Very often he may be called upon forty or even fifty times during the year by one family. Time and again he is called for the most trivial of complaints, since his presence is so easily obtained. What a shame and degradation that our noble profession should become so cheapened. *"O tempora, O mores!"*

Let us consider what little chance a young graduate now has on the East Side. If he happens to be a well-trained man from a good medical school, a hospital man and perhaps with a good preliminary medical education it is all the worse for him. He will not be given the chance to practise medicine legitimately. A fair competition would be conducive to his ethical progress, but when he discovers that commercialism has become the prime factor, it is not long before his lofty ideals are dragged and sullied in the dust. Especially is this true of the able but needy young practitioner. He soon discovers that the only way he can build up a practice is by getting lodges. Instead of devoting his spare time to perfecting himself in his medical knowledge, he is compelled to devise ways and means for obtaining societies. The iron heel of necessity compels him to become proficient in the invidious art of winning out at society elections. His medical mind becomes warped and instead of progressing ethically he gradually retrogrades into a proselyte of commercialism and a mere huckster of medical advice.

Still another element which harms both the lodge doctor and his lodge patients must be considered. What is the quality of medical advice and attention that the lodge doctor can give to his lodge patients? Let us say that he has reached the stage where he looks after eight or ten lodges. On a routine day he may see thirty or more lodge patients. Can he conscientiously examine each patient and make the proper diagnosis? That would be well nigh impossible, for after all it is only a question of human nature over again. He unconsciously—or consciously, perhaps—begins to discriminate against his lodge patients. He gives them a very superficial and cursory examination and prescribes for them with a snap diagnosis as foundation for his therapeutic advice; or, worse yet, he prescribes without any diagnosis and with merely an eye towards symptomatic relief.

As a natural result the lodge doctor becomes careless and slipshod in his medical ways. His diagnostic ability not only remains at a dead standstill but from "disuse-atrophy" retrogrades so far that his advice is of no more value than that of the corner druggist.

We are in too enlightened an age not to be able to remedy or at least make lighter most evils and the evil of lodge practice is one that can be solved and eradicated. To do this vigorous and strenuous action must be taken by the East Side physicians. In the main it is only by a return to their medical

ideals and "by grappling these ideals to their souls with hooks of steel" that they can solve this problem and straighten out the course of this medical boomerang.

142 Rivington Street.

THE KING'S EVIL.

By HORACE GREELEY, M.D.,

BROOKLYN, NEW YORK.

Once upon a time, as all orthodox fairy tales begin, it was a frequent occurrence for a terrestrial potentate to take with him to heaven governmental authority, as is evidenced by well-known instances in Grecian mythology, such as that of Saturn and his three sons, Jupiter, Neptune, and Pluto, several of whom, tradition states, were once rulers of well-defined districts of ancient Greece and even now astronomy preserves to most of the family a celestial inheritance.

Later on in this, which some might call the mythological age, the gods became more jealous of their prerogatives and, instead of permitting a pollution of their casts by admixture with mortals, frequently contributed to the parentage of the more illustrious men. Nearly all the heroes of Homer and the kings of Hellas boasted of blood of heavenly hue derived from peculiar connections of some one of their ancestresses, which, if with other than the gods, would have been as carefully concealed. But a la Mazeppa's Count Palatine, "A King, had reconciled him to the thing," they felt honored by even an ichorous taint.

As men grew less credulous, or perhaps less romantic, these claims gave way to that of selection by divine interposition, and, in Christian times at least, all early rulers were considered to have been chosen by a decree of the omnipotent and, upon assuming the crown, were anointed as a special sacrament as a sign of holy authority and general infallibility. Whenever even ordinary decency and a pretension to piety were possessed by the wearer of the purple, popular enthusiasm and craving for the extraordinary frequently credited the monarch with miraculous ability to cure disease; and, while all manner of ailments were originally supposed to yield to kingly interposition, it was in England that the belief finally crystallized into specialism, and tuberculous disease (producing swelling and ulceration) of the glands of the neck became known as the King's Evil, upon which the reigning majesty's touch was thought to exercise particular and peculiar curative power.

Edward, surnamed the Confessor, is regarded as the father of the procedure and after him most of his successors, down to and including Queen Anne, exercised the privilege and were credited with effecting good results.

William of Malmesbury, writing in A. D. 1100, 40 years after the Confessor's death, records: "A young married woman, but childless, was afflicted with swellings about her neck, and fell into bad health. Being commanded in her sleep to inquire for the bathroom of the king, she entered the palace, when the pious king, dipping his hands into the water, and stroking her neck, soon restored her to a happy state of health." And the same authority states that this prince was equally successful in many other instances. The person touched was usually given a small sum of money, to relieve his urgent necessities, but no particular coin, as later came to be the practice in the reign of Henry VII who bestowed upon each sufferer a gold "angel" (a coin which had upon one side a representation of an angel stamping upon a dragon) as an amulet, which was considered to continue the good influence of the magic touch with the patient indefinitely.

Although all of Edward's successors are not known to have practised the procedure, still it never was forgotten and varying with the character of the monarch it was given prominence or fell into disuse.

Henry VII, a great lover of ceremonial and religious parade, made the most of this inheritance and established a routine to be observed during the procedure, the chief part of which was the recital by an attending prelate of a prayer, modified from an old exorcism used to drive out devils.

Elizabeth, although a daughter of religious reformation, is said to have touched a great many for the cure of the disease, but first required one of her physicians to examine the case and to certify that the sufferer was actually afflicted with the Evil, and that he was either too poor to secure regular medical attendance or else was so seriously ill that the usual ministrations could offer no hope of betterment. It is recorded that a militant and irreconcilable papist, confined in prison for his opinions, developed a severe case of the malady, and was touched by the Queen for its cure, which was thereby effected so thoroughly and speedily as to completely win over the non-conformer who avowed that one possessed of such powers was most certainly an instrument of God, and that hereafter he would take his spirtual food from her hand. Elizabeth, however, would never claim infallibility in this particular, although flattered by, and glad to see, belief in it by others; and once during a royal progress was so besieged by would-be patients that she exclaimed in her usual hysterical hypochrondriacal way: "Why do these poor folk come to me? God only can cure them."

That canny Scot, James Stuart, whose anxious expectancy was eventually awarded with Elizabeth's crown, failed not to exploit every jot and tittle of his inheritance and did not neglect to show the new cunning his hand had gained. He was perhaps particularly pleased to parade this power before his old enemies in Scotland, later known as the Covenanters, who pretended to be greatly outraged by any assumption of spiritual authority by the King. It is recorded that in 1618 the Turkish Ambassador presented his young son to James and asked that the royal hand be applied, which the king graciously did, omitting the prayers usually offered during the ceremony. At the end of seven days the accomplished courtier returned to thank his majesty for the complete cure which, he most diplomatically claimed had been effected. The only change made by James in the ceremony, as inherited from Elizabeth, was to give a smaller piece of gold than before to each applicant.

Charles the First enjoyed great popular credit for the efficacy of his touch and appointed particular days whereon all the afflicted might repair to his healing hand; but to guard against those who abused the royal favor by frequent return to secure another gold piece, he required every applicant to present a certificate from his parish curate that he had not previously been touched. Later, while he was a prisoner of the Parliament's in Holmby House, so many people flocked to be touched that the Round Head government issued a proclamation decrying the practice as

most superstitious and abominable. After the King's execution it was claimed that the contact of various articles stained with his blood continued the cure in England.

Cavalier historians declare that whenever Cromwell attempted to exercise this holy regal power, instead of improving, the case always grew worse and rapidly failed, so seared was it by the regicide's noxious touch.

At the Restoration, Charles the Second, returning with that aureole lent by the romance of adversity and exile, found awaiting him a people reacting from overindulgence in puritanism, wildly enthusiastic in support of the divine right of a king and consequently most eager for a revival of his most holy office.

And it is he that carried the practice to its greatest extent. Registers were kept of all those touched and each individual before gaining access to the King was examined by a physician and given a ticket, and certain days and places were appointed for general rendezvous. Evelyn in his diary thus describes the ceremony under an entry of July 6, 1660: "His majestie began first to touch for ye evil, according to costome, thus: his majestie sitting under his state in ye banquetting house, the chirurgeons cause the sick to be brought or led up to the throne, where they kneeling, ye king strokes their faces or cheeks with both hands at once, at which instant a chaplaine in his formalities says 'He put his hands upon them and he healed them. This is said to every one in particular. When they have been all touched they come up again in the same order, and the other chaplaine kneeling, and having angel gold strung on white ribbon on his arm, delivers them one by one to his majestie, who puts them about the necks of the touched as they passe, whilst the first chaplaine repeats, 'That is ye true light who came into ye world.' Then followes an epistle (as at first a gospel) with the liturgy, prayers for the sick, with some alteration; lastly, ye blessing; and then the lo. chamberlaine and comptroller of the household bring a basin, ewer and towel, for his majestie to wash."

Charles frequently treated as many as 600 at a sitting (in 20 years of his reign there were recorded in the register some 100,000 cases) but notwithstanding his activity, a greater proportion of the population died from the disease, according to the mortality lists than under any other sovereign. Were the king's services required by persons of quality his majesty was always willing to attend them in their lodgings and apart from the common people.

Of course, many of those that flocked to the court to be cured came only out of curiosity, or for the gold piece to be obtained, but of those actually ailing it is to be presumed that some either got better from natural causes, or imagined that they had been benefited and so long as popular belief upheld the practice any caviling individual was sure to be drowned with lèse majesté clamor.

Queen Anne was the last of the English rulers to touch to cure, and one celebrated instance of her failure to heal was the case of Dr. Samuel Johnson whose throat she stroked when he was 4½ years of age, but who throughout his life suffered from the malady.

The English kings were imitated by their near rivals of France, who would not be outshone in Divine favor, and it was even claimed that the practice had originated with King Clovis some six centuries before Edward the Confessor's time; but it appears that Louis IX, St. Louis, in the 13th century, was the first French monarch to acquire the magic touch of healing, and almost every one of his successors up to the Revolution exercised it.

Francis I, although generally a very gay Lothario, was credited with very many cures and even after his foolhardiness had landed him a prisoner in Spain his poet said of him:

"The king applies his hand, diseases fly,
And though a captive, still the powers on high
Regard his touch, thus striking proof is given
That they who bound him are the foes of Heaven."

Of Louis XIII it was said that when he deputized to Cardinal Richelieu every other power, he only retained this because if he parted with his hand he could no longer pull candy.

A CASE OF TETANUS SUCCESSFULLY TREATED WITH MAGNESIUM SULPHATE.

By CHARLES D. FOX, M.D.,

PHILADELPHIA, PA.

As the general recognition of the value of any comparatively new method of treatment depends largely upon reports of cases, whether successful ones or not, the following case is reported as an addendum to a paper on tetanus which appeared in the Medical Record of August 13, 1910.

While playing near a stable, at Ambler, Pa., a boy of twelve years ran a splinter into the right great toe. The splinter was removed at once by the patient, but two days later, August 10, 1910, the wound became septic. After a period of incubation lasting eleven days stiffness of the jaw became apparent, and the following day the back was involved. Tetanic convulsions developed August 20. The boy was sent to the Hahnemann Hospital of Philadelphia, August 21, and the wound was completely excised and cauterized by Dr. W. Nelson Hammond. At this time trismus was almost absolute, decided opisthotonos was present, his temperature varied from 99 3/5° to 101 3/5°, and he was delirious. Besides these conditions he complained of considerable pain throughout his muscles, vomiting was frequent, he perspired profusely, and during the first night in the hospital five convulsions occurred with moderate embarrassment of respiration.

The first day in the hsopital he was given a subcutaneous injection of 3,000 units of antitetanic serum, and, at the same time, 1,200 units was injected into the spinal canal. Subsequently 3,000 units of the serum was injected every six hours, at first subcutaneously, and later by the intravenous method. Further treatment consisted in the administration of a saturated solution of sodium bromide, commencing with 5 drops every four hours, combined with chloral hydrate. At first it was attempted to give these drugs by mouth, but by reason of the frequent vomiting it was necessary to inject them into the rectum. The size of the dose of each of these two drugs was rapidly increased in an attempt to control the convulsions and general rigidity, so that on the third day the patient was receiving every four hours 7 grains of chloral and 40 drops of the solution of sodium bromide. In addition to these measures every evening for five days ⅛ grain of morphine was given by mouth.

August 22, 1910, the rigidity had become general, and was so marked that the abdominal wall felt boardlike. The patellar reflexes were greatly increased, and bilateral Kernig's sign had developed, but at no time did he present either the Babinski sign or ankle clonus. The convulsions were frequent and mild. Parenthetically, there seem to be two general types of tetanus: one in which the disease occasions well-developed tonic convulsions with little general rigidity in the intervals, while in the other variety the convulsions are rudimentary, but the rigidity is constant and extreme. It was to the latter class that this patient belonged.

As the patient continued to grow worse, and as the serum and hypnotic drugs were failing to control the development of the disease, 2 c.c. of a 25 per cent. solution of magnesium sulphate was injected into the spinal canal August 23, after removal of an equal quantity of cerebrospinal fluid. The effect of this injection upon the pulse and respiration was practically nil. Instead of occasioning an alarming drop in the respiratory rate, such as has occurred in other cases, the respirations increased from 26 to 32, while the pulse remained about the same—120 per minute. Not any immediate effects of this injection were noticeable, but four hours after the injection the upper and lower extremities were found to have become almost completely relaxed. There was little change, however, in the amount of rigidity of the abdomen and back. Instead of continuing to become worse the patient remained about the same as during the first twenty-four hours after the injection, so that further administration of magnesium sulphate was considered unnecessary.

About the seventh day after admission gradual improvement set in, and the serum was discontinued. At the same time the doses of chloral and bromide were progressively decreased so that four days later these, too, were discontinued. At present, September 14, the patient is entirely well, and will be discharged from the hospital in several days.

During the first week in the hospital the patient received 60,000 units of antitetanic serum. Of this 24,000 units were given by the intravenous method, 12,000 were injected into the spinal canal, and the remainder subcutaneously. Even though intravenous injection of the serum may not possess any therapeutic superiority over the subcutaneous method of administration of this agent yet it has a decided advantage in being much less painful, and in being less apt to be followed by a disagreeable local reaction.

As it is difficult to administer an amount of food sufficient to compensate for the excessive waste occasioned by the disease, and as trismus interferes greatly with the ingestion of food, ice cream was found to be a valuable nutriment in this case; particularly as the patient could not tolerate milk.

Even though the period of incubation was eleven days this case may be classified as a severe one, and until the beneficial effects of the injection of magnesium sulphate became apparent the outcome was considered dubious.

2126 Pine Street.

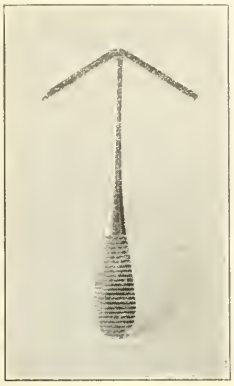
Meningeal Reactions in Scarlet Fever.—G. Paisseau and L. Milhit, on the basis of numerous lumbar punctures, come to the conclusion that irritative conditions of the meninges are almost always found in infections occurring in young people. The pressure of the cerebrospinal fluid was slightly increased, and a lymphocytosis was frequently present. In no instance were microorganisms found in the fluid.—*Bulletin de la Société de Pédiatrie de Paris.*

GUIDE FOR THE LATERAL SINUS LINE.

By EMIL AMBERG, M.D.,

DETROIT, MICH.

In the *Journal of the American Medical Association* of May 19, 1906, I published a simple method of finding an easily accessible portion of the lateral sinus. I called attention to the fact that an easily accessible portion of the lateral sinus may be found when we open that part of the mastoid process which is located in the direction of the line which divides into two halves the angle formed by the temporal line and the anterior border of the mastoid



process (an angle of about 115° in adults). Since that time I had occasion to verify the usefulness of this method, at least for adults, not only in my own cases. In order to facilitate the finding of the easily accessible portion of the lateral sinus I had constructed the simple guide depicted in the accompanying figure. One shank should be held over the anterior border of the mastoid process, the other over the temporal line. The handle of the guide gives the direction of the lateral sinus line. Even if the angle formed by the anterior border of the mastoid process and the temporal line should be somewhat different, the instrument is of service by allowing the same margin of deviation to both shanks. The length of the whole instrument is about 8.25 cm.

270 Woodward Avenue.

The Paratyphus Bacillus and Its Clinical Evolution.—E. Job and V. Raymond show that there are two distinct forms of symptoms as a result of the paratyphus bacillus, the acute gastrointestinal and the cholera type. The first form is characterized by vomiting, diarrhea, and choleraic symptoms. It is the result of gastrointestinal intoxication. Contagion may play a part in its causation. In the second form it acts like the bacillus of Eberth. It is most important to make a bacteriological diagnosis in these cases. When we have intoxication from meats, if the symptoms begin very rapidly, it is because the germs had begun to act in the body of the animal before it was killed. The germ is very abundant in the meat and acts at once on the organism. When it arises from water the incubation and evolution are very like that of typhoid. The number of germs is small, and the toxins or endotoxins are not present until the germs have multiplied. The author gives a case illustrating each of these forms of disease from the paratyphus germ.—*Le Progrès Médical.*

THE DIAGNOSIS OF POLIOMYELITIS IN THE PREPARALYTIC STAGES.

AT a symposium on poliomyelitis held in one of the medical societies of New York City a few years ago, one of the speakers emphasized the importance, in treating this disease, of promoting active elimination through all the channels of the body during the period of invasion. When questioned as to how one may recognize the presence of poliomyelitis before paralysis manifests itself, the speaker admitted naturally that this was impossible, but advocated the eliminative treatment in all cases of suspicious acute illness in children, particularly when poliomyelitis is prevalent. The recent experimental studies on this disease have brought to light evidence upon which a diagnosis might be made some time before the onset of paralysis. The importance of making an accurate early diagnosis is manifest when one realizes the impossibility of checking the process after paralysis has set in, for by this time the virus has already spent its force. In the Monthly Bulletin of the Massachusetts State Board of Health for June, 1910, W. P. Lucas, discussing the diagnosis of infantile paralysis in the prodromal and early acute stage, states that the results of the New York investigation of the prodromal symptoms agree completely with those of animal experimentation. The most noteworthy signs are change of disposition, restlessness, and irritability, or apathy, appearing several days before any other symptoms. The paralysis may even be preceded for several days by delirium and convulsions, or epileptiform attacks. In the exceedingly irritative cases the diagnosis of cerebrospinal meningitis is frequently made. In the prodromal stage not an uncommon finding is pain, most often in the back along the spine or in the joints of the extremities which may show swelling and tenderness. Headache, general or frontal, is frequently present, and this is often accompanied by rigidity of the neck. Suspicion should at once be aroused, if with any of these nervous symptoms there is associated coryza, bronchitis, or sore throat. The temperature is not typical and is of little use as a guide.

In addition to these clinical manifestations, experimental and clinical study has revealed certain diagnostic points that may be obtained from the examination of the spinal fluid and blood in the prodromal and acute stages of the disease. Using virus obtained from Flexner, the author was able to produce paralysis in three monkeys and to transfer paralysis through two subsequent series of inoculations. The study of the blood brought out at least two very interesting facts. The normal differential count was, multinuclears, 60 per cent.; large and small uninuclears, 25 per cent.; lymphocytes, 12 per cent.; eosinophiles, 3 per cent. In the acute stage there was a moderate and constant lymphocytosis, the count being multinuclears, 40 per cent.; large uninuclears, 15 per cent.; lymphocytes, 40 per cent.; eosinophiles, 5 per cent. Parallel with this lymphocytosis there was a marked and constant leucopenia. This drop in the white count continued throughout the acute stage. The leucocyte count did not change during the incubation period, but did change occasionally during the irritative or prodromal stage when there was a marked or moderate drop in the white count.

The spinal fluid showed even more marked and characteristic findings during the incubation period, prodromal, and acute stages, disappearing about the time that the acute symptoms begin to subside, being at their height either in the prodromal stage or on the first or second day of the acute stage. During the incubation period there is a marked increase in the amount of fluid obtained from lumbar puncture, and in its cellular content, there being 100 to 300 cells per cubic millimeter. These cells are mainly of the large uninuclear type, with some multinuclear cells and lymphocytes. In the prodromal stage there is even a more marked increase of the cells, often reaching 1,000 per cubic millimeter. In this stage, also, multinuclears are still present, in some cases as high as 60 per cent., though the large uninuclears and lymphocytes are very evident. In the early acute stage the increase in cells is very marked, these being now mostly of the lymphocytic or very early form of cells, and sometimes very hard to place, as they are apparently undifferentiated cells. As the cells decrease in number the multinuclears begin to return, and at the end of a week or ten days there are very few cells present, mostly large uninuclears with a few multinuclears. In the prodromal and acute stages there was at times a fibrin clot which would disappear fairly early during the acute stage.

These experimental findings were closely paralleled by those observed in four cases of acute poliomyelitis in children. The important points revealed by blood examination in the acute stage were the marked leucopenia and lymphocytosis, while the examination of the spinal fluid, which was increased in amount in all the stages, showed an increase in the numbers of cells, the relative proportions of the different kinds varying in the different stages.

The importance of these investigations cannot be overestimated. The ability to make an early diagnosis will render possible the prompt institution of measures designed to stay the progress of the infection, although such measures may have but slight effect in limiting the resulting paralysis. Early diagnosis will be of still greater value when the antitoxic serum for poliomyelitis will have been discovered.

PURIFICATION OF WATER BY OZONIZATION.

Certainly one of the chief aims of sanitary science is to procure a pure water supply. When this object is achieved, or when a water supply can be obtained which is free from harmful germs, a great victory will have been won. As yet we do not seem to be near realization of this ideal state of affairs. It must be remembered that water is largely responsible for epidemics of typhoid fever and of cholera, to mention the two most serious waterborne diseases, and typhoid fever is by no means extinct in the United States. Sand filtration, and especially slow sand filtration, has done much to check the spread of typhoid fever, but, after all, filtration, of every kind, has its limits; it is filtration and not sterilization.

Recently, a method of purifying water has come to the front, which, perhaps, up to the present time, has not been used on a sufficiently large scale, nor for a long enough period of time to justify any very decided assertions as to its merits. The ozonization of water by means of electricity as a sterilizing agent, is the method to which reference is made. The principle of purifying water by ozone has, of course, been known for a considerable period of time, and it has even been used on a small scale for some years. Its adoption for purifying the public water supply of a fair sized community dates back about seven years. Paderborn, in Germany, in 1902, was the first town of any size to install a system for purifying water by ozonization, and electricity was the agent utilized to manufacture the ozone. The principle of preparing the ozone by electricity is the same everywhere, but the particular method followed in Paderborn and other German towns in which the system is in vogue is as follows: Air enclosed in parallel plates is forced by means of a blowing apparatus through a discharge chamber, where it is subjected to currents of electricity at a high voltage. The velocity of the passage of air through this chamber is regulated in such a manner that when the air leaves the chamber it is impregnated with enough ozone to sterilize water. The water which is to undergo the sterilizing treatment by ozone is first passed through a special sand filter to remove all solid matter in suspension. The water is then pumped into towers and as it passes down through the towers the ozone is forced into them from below and brought into close contact with the water, destroying the bacteria contained therein. The water thus treated and freed from bacteria passes out from the towers and is fit for consumption. Wiesbaden has had an ozone plant for some years which is said to have given satisfaction.

The results of treating water by ozone have been tested experimentally at Koch's Institute and at the Imperial Health Bureau in Berlin. Water was taken from the Spree and largely infected with cholera germs. The water was passed through the ozone plant and an examination showed that the disease-bearing bacteria had been destroyed. Similar results are said to have been obtained with water infected with dysentery and typhoid germs to the number of 600,000 bacteria per cubic centimeter, both at Koch's Institute and at the Imperial Health Bureau, Berlin.

At the suburb of St. Maur, Paris, where from the River Marne is drawn a goodly portion of the Paris water supply, an ozonization plant has been working for some little time. The Marne is highly polluted by sewage, and a preliminary clarification of the water through beds of sand and gravel is necessary before the ozonizing process is commenced. So well satisfied are the Parisian engineers with the result of the ozonization method of purifying water, that it is stated that an ozone purification plant is to be installed at Paris to treat 24,000,000 gallons a day.

The system has been investigated by numerous high authorities, most of whom appear to be convinced of its remarkable sterilizing properties, but a good deal of scepticism still exists as to its applicability on a large scale, and it has also been considered that the cost of the system would greatly exceed that of the filtration methods. However, it really does appear that purification of water by means of ozone can be conducted in a satisfactory manner on a very large scale and that its cost is not prohibitive. The ozonization of water is, however, essentially a sterilizing process and not a filtration process, and that public water supplies, unless the water be peculiarly clear, must undergo some kind of filtration before they are subjected to ozonization.

Some of the advantages of ozonization are obvious. The method sterilizes effectively and frees water from offensive odors and tastes and from objectionable colors. That it does this is sufficient to recommend its use in all large cities. It is an open question, as Rideal said recently in reference to the ineffectiveness of filter systems in preventing typhoid fever, whether it was not advisable that these methods should be supplemented by a process of sterilization. There is no doubt that filtration has been tried and has been found wanting in many respects. Ozonization of water by electricity may not be the best method but it would seem that it is at least one which in the future will have to be considered.

The New Hospital of the Rockefeller Institute.

The opening of this hospital on October 19, 1910, marks a new era in the annals of scientific medicine in New York City. Situated near the Laboratory buildings and open on all sides to light and air, this hospital, with a separate building for contagious cases, represents the most modern ideas in hospital construction and is fitted with all necessary administrative and sanitary appliances. Although the main building is eight stories in height, only four floors are used for patients; in spite of the complete equipment there are only seventy beds. The reason for this limitation is that the hospital is primarily for the purpose of advancing the knowledge of clinical medicine, especially in the nature, diagnosis, and treatment of disease; and that this object can be best attained by the intensive study of a few patients rather than of a great many. The purpose is to concentrate the energies of the institution upon three or

four medical problems at a time, and to admit at any time only such cases as are the subject of study. This purpose will also be furthered by the fact that the medical staff, which is relatively large, will be paid, and each member will devote all his time to the service of the hospital. One entire floor of the building is devoted to clinical laboratories—chemical, biological, physiological, and photographic. The wards are large, but each contains only seven beds. One side of each ward consists of glass, sliding into concealed pockets, so that all the beds may be wheeled out at once and the patients be kept out of doors at any time. An open loggia or roof at each end of the building is large enough to receive all the beds at once when they are wheeled out. There are really eleven roof spaces, so that the greater proportion of the area provided for patients is out of doors.

The Babinsky Sign in Diphtheria.

The investigation of the occurrence of the Babinsky sign in the course of diphtheria may serve to shed some light upon the nervous manifestations of this disease. Kiroff was the first to call attention to the occurrence of this phenomenon in diphtheria, although its presence had already been noted in typhoid fever and scarlatina. Basing his observations on the study of 877 cases of diphtheria in which the plantar reflex was investigated, J. D. Rolleston, reporting his results in the *Review of Neurology and Psychiatry*, July, 1910, states that the Babinsky sign was found in 19.6 per cent. of all cases. The extensor response is not confined to infancy, but is found, though with diminishing frequency, with advancing age, especially after the eighth year. Essentially a phenomenon of the acute stage, it is not pathognomonic of diphtheria, occurring in other infectious diseases, especially typhoid fever, lobar pneumonia, and scarlet fever, but its greater frequency in diphtheria than in non-diphtheritic angina imparts to the sign a certain value in diagnosis. It is more frequent in the severe than in the mild forms of diphtheria; this is shown by the fact that in the cases in which the Babinsky reflex occurs, the throat symptoms are severer, and there is a higher mortality and greater frequency of paralysis and albuminuria. To its presence, therefore, a definite diagnostic value is attributed. Rolleston believes that the sign is evidence of the occurrence of a transitory perturbation of the pyramidal system by the circulating toxins of a nature similar to the mild degree of meningeal reaction frequently occurring in acute infections.

News of the Week.

Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission for the month of August, 1910, gives the death rate for the month among employees as 13.04. In 1907, the death rate for the same period was 27.59; in 1908, 11.39; and in 1909, 10.28. The annual average per thousand of deaths in the cities of Panama, Colon, and the Canal Zone, including both employees and civil population, was 19.85 for August, 1910; 16.20 for August, 1909; 26.65 for August, 1908; 33.75 for August, 1907; and 64.12 for August, 1906. For diseases the annual average per thousand of employees for the month was: White, 5.28; colored, 8.11. For 1909, the figures were: White, 6.19; colored, 6.10. No cases of yellow fever, smallpox, or plague were brought to or originated on the Isthmus during the month.

Lectures on Sanitation.—A course of lectures on sanitary science will be given this year by Columbia University in the Horace Mann Auditorium, at Broadway and 120th street, New York, on Monday afternoons at five o'clock. Dr. Hermann M. Biggs of the Department of Health delivered the first lecture on October 10, on The Development of Public Health Work, and on October 17 Dr. C. E.-A. Winslow spoke on Water Pollution and Water Purification. The other lectures of the course will be as follows: October 24, Clean Streets as a Factor in Public Health (lecturer to be announced); October 31, Collection and Disposal of Municipal Waste, Dr. George A. Soper; November 7, Communicable Diseases, Diphtheria, Typhoid Fever, Scarlet Fever, etc.—Their Transmission, Dr. W. H. Park; November 14, Communicable Diseases—Their Prevention, Dr. Park; November 21, Some Examples of the Control of Infectious Diseases, Dr. Simon Flexner; November 28, The City Milk Supply and its Control, Dr. Ernst Lederle; December 5, Flies and Other Insects as Carriers of Disease (lecturer to be announced); December 12, Housing and Health, Lawrence Veiller; December 19, Tuberculosis: The General Problem; the Organized Campaign Against the Disease, Dr. Livingston Farrand; January 9, Tuberculosis as a Social Problem; Methods of Treatment, Dr. James Alexander Miller; January 10, What the Teacher Should Know of the Tuberculosis Problem, Dr. S. Adolphus Knopf; What the Teacher Could Do Toward the Solution of the Tuberculosis Problem, Dr. Knopf. The lectures are free and open to the public.

City Death Rate.—For the week ending October 8, there were 1,333 deaths in the City of New York, four less than in the corresponding period of the previous year. This gives a death rate for the week of 14.48 per 1,000 of population in 1910, and 15.28 in 1909. Pulmonary tuberculosis caused 155 deaths, an increase of 11, and pneumonia 108, an increase of 2. Among children under five years of age there were 468 deaths, of which 364 were among infants under one year of age. Seventeen deaths were caused by typhoid fever, which is seven less than last year.

Rockefeller Institute Hospital.—The new hospital attached to the Rockefeller Institute was opened for inspection on October 17 and 18, and for the reception of patients on Wednesday, October 19. The hospital contains seventy beds and will be used for the treatment of selected cases only. For the present, cases of infantile paralysis, pneumonia, heart disease, and disorders of metabolism will be received for study. The staff consists of Dr. Rufus I. Cole, Director; Dr. Christian A. Herter, Physician to the Hospital; Dr. C. C. Robinson, Resident Physician, and four internes. The service will be entirely free.

Crowded Tuberculosis Wards.—The overcrowded condition of the wards used for the treatment of cases of tuberculosis in the Metropolitan Hospital on Blackwell's Island, N. Y., was brought to the attention of the State Board of Charities on October 12. As a result the commissioners decided that the city ought at once to provide for increased accommodations on Blackwell's Island and to complete the Sea View Hospital on Staten Island. It was pointed out that the new building soon to be opened will only temporarily relieve the congestion, if at all.

New Research Laboratory.—In a report of

the work done in the research laboratory of the Department of Health, New York, Dr. Hermann M. Biggs, chief medical officer, urges the establishment of a new research laboratory to be devoted to the study of specific therapy and preventive medicine. The cost of such a laboratory, including salaries, equipment, and supplies, is estimated as about $45,600 annually.

Syracuse University.—A number of changes have been made in the corps of instructors in the College of Medicine of Syracuse University. The course in Anatomy will be conducted by Prof. Henry W. Stiles, until recently of Tulane University, New Orleans, assisted by Dr. Robert H. Haskell, formerly of the University of Michigan. A course in applied anatomy will be given during the second year. Prof. H. Burton Doust will have charge of the course in Materia Medica.

Diphtheria at Hamilton College.—An epidemic of diphtheria has been reported at Hamilton College, Clinton, N. Y. Thirteen cases have been isolated, and a number of men are under observation.

Yellow Fever in Venezuela.—A dispatch from Venezuela to the State Department contains the information that yellow fever has appeared at Puerto Cabello.

Charitable Bequests.—St. Luke's Hospital, Chicago, receives a bequest of $25,000 outright, under the will of the late Mrs. John Mason Loomis of that city. The Children's Memorial Hospital receives $10,000 also. An additional $25,000 will go to St. Luke's Hospital in 1925, provided a brother of the testator has not been found by that time.

Aldermen and Straus Depots.—The New York aldermen on October 11 passed a resolution urging Mr. Nathan Straus "to continue his splendid efforts in behalf of the poor and needy in the supply of pure milk." There was but one dissenting vote.

Open-Air Schools.—Montclair, N. J., inaugurated its first open-air school on October 10, the class meeting in a large tent on spacious grounds. Twenty-one pupils were in attendance. The sides of the tent are open, and the children will be provided with special warm clothing and sitting-out bags for the winter weather.

A special class for tuberculous children will also be opened shortly on the grounds of the Consumptives' Home, in Brooklyn, N. Y. The class will be an annex to the public school nearby.

Ambulance Mishaps.—An ambulance of the Kings County Hospital, Brooklyn, while answering a call on October 9, was struck by a trolley car of the Nostrand Avenue line and wrecked. Both the driver and the surgeon were thrown out and seriously injured.

An ambulance from the Lying-In Hospital, while taking a patient to the hospital on October 12, ran down and injured a man who attempted to cross in front of it. During the attendant commotion the driver of the ambulance collapsed, and the patient in it gave birth to a child before the hospital could be reached. At last reports all concerned were on the road to recovery.

Dr. Bulkley's Lectures.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give a twelfth series of clinical lectures on diseases of the skin in the Out-Patient Hall of the hospital on Wednesday afternoons, from November 2 to December 21, 1910, at 4.15 o'clock. The course will be free to the medical profession.

Dr. T. D. Crothers of Hartford, Conn., will deliver a series of lectures on Alcohol and Drug Addiction, at the American Medical College of St. Louis, on December 8, 9, and 10, 1910. The lectures will be open to the public as well as to members of the medical profession.

The Tenth International Congress of Pharmacy met in Brussels on September 1 to 6, 1910. Twenty foreign countries were represented by official delegates, the United States, Argentina, Chile, Venezuela, Guatemala, San Salvador, and Haiti, being included. At the opening session the work of the congress was outlined, two subjects being presented as of the greatest international interest: (1) the further unification of the pharmocopeias, with especial reference to the adoption of uniform methods of assay of important drugs; and (2) the control of the sale of specialties (proprietary medicines) from the standpoint of public health as well as that of the material interests of the pharmacists. For the succeeding days the congress divided into a scientific and a professional section, at each of which various subjects were taken up for discussion. At the concluding session the entire congress again met and voted upon a number of resolutions which had already been adopted by the separate sections. The first resolution presented by the scientific section related to the unification of the methods for the assay of crude drugs and of galenical preparations and for the determination of physical constants. The Belgian government was requested to call an international conference for the unifying of the methods of analysis of the heroic medicaments. In the matter of alkaloidal assays the resolution recommended the adoption of gravimetric methods. The second resolution related to the international unification of the reagents used in pharmacopeial work, pointing out that such a unification would aid in securing uniform analytical results. The third set of resolutions related to the control of antiseptics, with special reference to securing commercial honesty and safeguarding the public, the opinion being expressed that such preparations should not be placed upon the market until they had been officially examined, both chemically and bacteriologically, and had received the approval of the departments of public health; that their efficiency should be determined and the claims made by the manufacturers investigated; that the amount of their active ingredients and their bactericidal strength should be stated, and that the sale of those claiming to possess therapeutic properties and of those containing poisons, the sale of which is legally restricted, should be limited to pharmacists. The fourth resolution related to the introduction into schools of pharmacy of courses on the analysis of certain physiological and pathological secretions, especially of the feces. The fifth resolution related to the preparation of galenicals by pharmacists, who were urged to make these preparations themselves. The professional section presented resolutions dealing with the control of the sale of medical specialties, which it thought should be confined to pharmacists, with the formation of an international pharmaceutical federation having for its purpose the protection of pharmacy as a profession and as an applied science, with the representation of practical pharmacy on pharmacopeial commissions, and with the limitation of the number of pharmacopeias. It was also resolved to make the question of patents and trade marks one of the subjects for discussion at the next congress.

New Jersey State Pediatric Society.—The second general meeting under the auspices of this society will be held in the Hotel Marlboro, Asbury Park, N. J., on Thursday evening, October 27, at 8.30 o'clock. Dr. Linnaeus Edford LaFetra, of New York City, will deliver an address on "Cardiac Affections in Childhood."

The Pathological Society of Philadelphia.—At the annual meeting, held October 13, Dr. David Riesman delivered the president's address, in which he reviewed the work of the Society for the year. An election of officers was held and resulted as follows: *President,* Dr. David Riesman, reelected; *Vice-Presidents,* Dr. A. O. J. Kelly, Dr. A. J. Smith, Dr. J. Sailer, and Dr. H. A. Hare; *Secretary,* Dr. H. E. Goodman; *Treasurer,* Dr. C. Y. White; *Recorder,* Dr. F. H. Klaer; *Curator,* Dr. Howard T. Karsner.

The Norfolk (Virginia) Medical Society at its meeting on October 4 elected the following officers: *President,* Dr. Israel Brown; *Vice-President,* Dr. N. G. Wilson; *Secretary-Treasurer,* Dr. Harvey Baker.

The Lexington County (South Carolina) Medical Society held its annual meeting on October 3 when the following officers were elected for the ensuing year: *President,* Dr. R. E. Mathias of Irmo; *Vice-President,* Dr. Frank G. Roberts of Lexington; *Secretary-Treasurer,* Dr. J. J. Wingard of Lexington.

The Kentucky State Medical Association at its annual convention at Lexington, recently, elected officers for the ensuing year as follows: *President,* Dr. J. C. Carpenter of Stanford; *Vice-Presidents,* Dr. J. W. Pryor of Lexington; Dr. B. E. Giannini of Coalmont; and Dr. G. E. Hancock of Henderson; *Secretary,* Dr. A. T. McCormick of Bowling Green; *Treasurer,* Dr. W. B. McClure of Lexington; *Delegate to the Meeting of the American Medical Association,* Dr. Curran Pope of Louisville. The next annual meeting will be held at Paducah in October, 1911.

The New Mexico State Medical Association opened its annual meeting at Albuquerque on September 29. Officers for the ensuing year were elected as follows: *President,* Dr. Francis T. B. Fest of Las Vegas; *Vice-Presidents,* Dr. R. L. Bradley of Roswell, and Dr. Leroy S. Peters of Silver City; *Secretary,* Dr. George S. McLandress of Albuquerque. Dr. McLandress was also elected editor of the medical journal.

Professor Miguel Bombarda, who was recently assassinated at Lisbon, was best known to foreigners by his work as General Secretary of the Fifteenth International Congress, which met at Lisbon on April, 1906. His genius for organization made the Congress one of the most successful ever held, and at its close his efforts were fittingly recognized by the late King Carlos who bestowed upon him the lilac ribbon, the gold chain, and the crimson cross of the Order of Santiago. Whether or not any political significance attaches to his death has not become known. By some the assassin is said to be merely a madman, a former patient at the Rillafolles Hospital, with a fancied grievance against Professor Bombarda, the chief physician in charge of the asylum.

Obituary Notes.—Dr. John V. Shoemaker of Philadelphia, professor of materia medica, pharmacology, and therapeutics, and clinical professor of diseases of the skin in the Medico-Chirurgical College of Philadelphia, died at his home of nephritis, on October 11, aged 58 years. Dr. Shoemaker was graduated from Dickinson College in the class of 1872, and from the Jefferson Medical College in the class of 1874. Immediately after graduation he became a demonstrator of anatomy in the latter institution, and shortly afterward lecturer on anatomy and diseases of the skin in the Philadelphia School of Anatomy. He aided in forming the Jefferson Quiz Association, and was quizmaster in materia medica and therapeutics. In 1883 he was made lecturer on diseases of the skin in the Jefferson Medical College, and in 1886 was elected professor of dermatology in the Medico-Chirurgical, a few years later becoming also professor of materia medica, pharmacology, therapeutics, and clinical medicine. He was the founder and for many years the editor of the *Medical Bulletin* and a liberal contributor to current medical literature, and was the author of several well known textbooks. Dr. Shoemaker was a member of the American Medical Association and of the Pennsylvania State and Philadelphia County Medical Societies.

Dr. De Forest Willard of Philadelphia, Pa., a graduate of the Department of Medicine of the University of Pennsylvania in the class of 1867, died at his home, on October 15, of double pneumonia. Because of failing health Dr. Willard had resigned the chair of orthopedic surgery in the University of Pennsylvania only a short time ago. He had held many offices of honor in medical circles and was an ex-president of the American Surgical Association, the American Orthopedic Association, the Philadelphia Academy of Surgery, and the Philadelphia County Medical Society, and an ex-chairman of the Section on Surgery of the American Medical Association. He was also a Fellow of the College of Physicians of Philadelphia, surgeon to the Presbyterian Hospital, consulting surgeon to the Germantown, Jewish, and Phœnixville Hospitals, and consulting surgeon to the Widener Memorial School for Crippled Children.

Dr. Joshua R. Morton of Allentown, Pa., a graduate of the Medical Department of the University of Pennsylvania in the class of 1871, died at his home on October 9, aged 61 years. Dr. Morton practised his profession for some time in Petersburg, Va., but later entered into business. He was for many years a member of the Allentown school board, and for the past year its president.

Dr. Frank Blair Olhausen of Harrisonburg, Va., a graduate of the University College of Medicine of Richmond, in 1898, and a member of the Virginia State and Rockingham County Medical Societies, died at his home of cirrhosis of the liver on October 8, aged 34 years.

Dr. Herbert O. Smith of Shakopee, Minn., a graduate of the Hahnemann Medical College and Hospital of Chicago in the class of 1881, and a member of the Minnesota State and Scott County Medical Societies, died suddenly of apoplexy at his home on October 4, aged 52 years.

Dr. William H. Woodbury of Chicago, Ill., a graduate of the Hahnemann Medical College and Hospital of Chicago in the class of 1866, died at his home on October 6, aged 85 years.

Dr. William H. Riley of New Orleans, La., a graduate of the Medical Department of Tulane University of Louisiana in the class of 1861, a regimental surgeon in the Confederate Army during the Civil War, died at his home on September 30, aged 72 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CONFERENCE ON HOSPITALS—EHRLICH'S REMEDY—THE PIONEER OF VENTILATION—HEALTH CARAVAN CRUSADE—RONALD ROSS'S NEW BOOK—ISOLATION OF TYPHOID—METALLIC RADIUM—SIR CHARLES CAMERON.

LONDON, September 30, 1910.

YESTERDAY the first conference of the British Hospitals' Association was opened at Glasgow University, Mr. Hedderwick of the Royal Infirmary presiding. Several papers were read and discussed, and then on adjournment the hospitals and infirmaries of Glasgow were visited.

The position of hospitals in relation to the profession and education, as well as to the Poor Law and charities, was the subject of a paper by Mr. C. S. Loch. He pointed out some of the changes that had occurred in the last forty years and which he thought implied a necessity for reorganization in reference to these relations so as to bring about better remuneration for medical men, better division of labor among institutions for the sick, and better association in charity. In discussion Mr. Cunningham deprecated too much State aid, while Professor Jones held that it was desirable that the community should make the greatest and most economical use of the highest medical skill.

The abuse of hospitals was the subject of a paper by Mr. Scott Finnie, of the Aberdeen Royal Infirmary. He admitted that many persons improperly availed themselves of free treatment. The natural result was the danger of alienating the sympathy hitherto enjoyed by hospitals, injury to the profession, delay in admitting deserving cases, and demoralization of the community. He suggested a reorganization of medical relief on some plan which would conserve the interests of the really poor and deserving and help those who could not wholly provide for themselves. To this end a special conference might be held. Colonel Roxburgh admitted abuse, and said paying hospitals would be welcome in Glasgow, but they could not have paying departments in their present institutions. Mr. Blakie of the Edinburgh Infirmary feared that to start paying hospitals would dry up at the source a good deal of the financial help on which they relied at present.

There is still some excitement about Prof. Ehrlich's new remedy, 606, the brief name for the chemical formula signifying dioxydiamido-arsenobenzol. Many are anxious to try it, but as many or more regard it as rather risky and are watching the reports. Thus, although there is something of a boom, here and there, it is nothing to be compared with that which followed the announcement of tuberculin.

I have a case under observation which has been injected, and although he had to keep his bed longer than has been generally advised, on account of the intense pain and febrile reaction, he is now cheerful enough, and ready to undergo a second time of torture if only he can attain a cure. He is a medical man himself and watching his case attentively. He was infected some years ago from a midwifery case attended while he had a scratch on his finger.

Dr. D. F. Harris, lecturer on physiology at the University of Birmingham, gave a lecture at the Midland Institute on the 15th, on the "Pioneer in Hygiene of Ventilation"—the Rev. Stephen Hales, M.A., D.D., F.R.S., who was as much perhaps a pioneer in other branches of knowledge, especially in the experimental method of studying physiology. He is much remembered as the designer of ventilators, though that is only a result of his scientific investigations which demonstrated the necessity of a constant change of air in the neighborhood of all living things—both animal and vegetable. His numerous researches extended beyond physiology, and he was in fact a pioneer in sanitation generally as well as in ventilation. Still it is in the last-named branch that he conferred so great benefit on his fellows, not only of his own age, but for all time. Dr. Fraser did not seem to think much of him as a pastor; at least he said we did not know much of his capabilities as such, but it was certain he had a great solicitude for men's bodies. He introduced a water supply into his parish and contrived to ventilate his church. He wrote a pamphlet on the abuse of alcohol—probably the first of the kind—published in 1734, entitled "A Friendly Admonition to the Drinkers of Gin, Etc." This Dr. Fraser admitted would "entitle him to rank as a pioneer in the advocacy of measures of practical hygiene." May we not add of practical morality, too?

The Health Caravan Crusade is going strong and to-morrow another caravan is to be dedicated to the work in East Anglia. It is equipped entirely by women and a qualified woman doctor will deliver the lectures. The first caravan has for six weeks been touring the western counties. In a score of towns and villages lectures with cinematograph pictures for illustration have been given from the van and printed sheets of advice how to preserve health and fight consumption have been freely distributed. The hygienists and doctors supporting the movement are convinced that much of the advice has fallen on fruitful soil. A third van is to be started in three of the London parks by permission of the County Council, and I am told that a new invention will enable the pictures to be seen by daylight. The Caravan movement is unique in not appealing to the public for funds, but is carried on by the Women's Imperial Health Association.

The new work by Major Ronald Ross is a cyclopedia treatise on malaria, dealing with its origin, manifestations, distribution, and prevention in the most authoritative and complete manner. It contains also contributions from Professor L. O. Howard and reports of special work in all malarial countries. Major Ross speaks of himself as a compiler because he has gathered first-hand information from many observers, but the focusing of all these deserves a more important title, especially as his own original work as an investigator is of so great scientific value. Malaria he considers has profoundly modified the history of the world by rendering to a great extent "the tropics unsuitable for the full development of civilization." The date of the discovery of the parasites he puts at 1869. It is a hopeful point that the drainage and filling up of pools in which larvæ are present have often rendered more extensive schemes unnecessary.

It is interesting to notice that the isolation of radium has been achieved by Madame Curie, whose work in reference to it is so well known. It was in collaboration with M. Debierne that the result was attained, as stated to the Paris Academy of Sciences on the 5th inst. The metal is possessed of great energy, oxidizes rapidly in the air, and burns paper

put in contact with it. It also decomposes water and seems to have a sort of magnetic attraction toward iron.

A case of typhoid occurring in one of the prisons illustrates the difficulty of tracing cases to their origin. The man had been at work in the prison for several months but no other inmate had had the disease for months before his admission. The water supply cannot account for our isolated case and the drainage is reported to be efficient. We do not admit an origin *de novo,* so it looks as if some contaminated article of food had gained entrance to the dietary, but then other prisoners would surely have been affected. Even a typhoid carrier would hardly have had access to a single person's food out of a number under similar conditions.

To-day Dublin is honoring itself and Sir Charles Cameron by conferring on him the freedom of the city for which he has done so much. Its reputation in public health matters was low enough when Sir Charles began his labors half a century ago and he has steadily raised it to its present level.

Immunity with Special Reference to Vaccine Therapy. T. Leary.
Types of Graves' Disease. J. G. Mumford.
Hysteria—With Autopsy. W. R. Woodbury and C. Reed.

Immunity and Vaccine Therapy.—T. Leary states that by artificial stimuli we have not succeeded in adding to the varieties of response which are exhibited against natural stimuli. The types of immunizing responses to stimuli are relatively few. A person who is infected with a pathogenic organism is producing sufficient amboceptor for his needs; what his blood lacks is complement, and as yet there is no means of artificially supplying this need. For these reasons the so-called bacteriolytic sera are failures, with the exception of Flexner's antimeningococcic serum, which is in a class by itself. In applying the principles of vaccine therapy it is noted that the ideal immunizing response can be produced without the toxic negative phase. Physiological doses of vaccines should be followed by an immediate production of antibodies without toxic action. Certain tissues exhibit a special immunity against infection. Most important among these are the muscles. The author recommends the injection of vaccines into muscle or into the intermuscular connective tissue. *Staphylococcus aureus* vaccine, in addition to provoking the ordinary specific immunizing response, seems to possess the power of stimulating an increase in general resistance. In general infections vaccines are harmless. This was indicated in a case in which, through error, 10 c.c. of *Staphylococcus pyogenes aureus* vaccine containing 10,000,000,000 organisms were injected at one time as an initial dose, which is forty times the standard initial dose. No harm resulted. In a second case the same dose produced a temporary collapse with prompt response to heat and stimulation. One objection raised against vaccines has been that persons undergoing infection are in an anaphylactic state, and therefore hypersusceptible to intoxication. This is a purely theoretical danger, as is evidenced by the infrequency of serious results following the use of diphtheria antitoxin. The evidence seems to predominate that pneumococcus vaccine is a distinct addition to our armamentarium. Vaccine treatment in surgical conditions does not do away with the necessity for intelligent surgery. With infections along some mucous surfaces vaccine therapy is less successful than elsewhere. Gonococcus vaccine has little influence on urethral infections, but a freshly prepared gonococcus vaccine made from first cultures from fresh cases gave prompt results in gonorrheal rheumatism. In colon bacillus infection of the kidneys, vaccines relieve intoxication and eliminate fever, but local infection persists. Staphylococcus vaccine is now accepted as the standard method of treatment of local conditions due to this organism. Erysipelas responds in most cases promptly to an autogenous vaccine. In a large percentage of cases of rheumatism treated there was prompt relief of pain and other symptoms after the empirical use of autogenous throat cultures containing a mixture of pneumococcus and streptococcus. The treatment of the associated infection in tuberculosis with autogenous vaccines in which the streptococcus and pneumococcus usually predominate is accompanied by diminution of temperature and relief of cough and night sweats, followed by increase of weight. Toxic symptoms arising from a relatively slight infection with *Bacillus coli* can be relieved usually within a few hours. The exhaustion caused by this organism in the late stages of typhoid fever is relieved together with the disappearance of a septic temperature by the use of an autogenous vaccine. The use of tuberculin is associated with dangers which make extreme caution necessary in its exhibition.

Types of Graves' Disease.—J. G. Mumford reports two dissimilar cases of this condition, one typical and the other atypical. The former was that of the gradual onset of dyspnea, dyspepsia, pain, and nausea after eating and a state of continual apprehension. After the persistence of these symptoms for two years there developed mild tremor of the fingers. A year later the characteristic symptoms of enlarged thyroid, exophthalmos, and tachycardia developed. During the next fifteen months vigorous medical treatment was employed, chiefly with the administration of neutral hydrobromate of quinine in five grain capsules three times a day. This produced great relief during the early months; later the shock of grief caused the reappearance of all the former symptoms in an aggravated form. The case now presented all the symptoms of acute hyperthyroidism, and a radical operation was performed, the patient being brought to operation practically without her knowledge, in order to ensure a calm state of mind. The operation was successful and the most striking result was the calm, tranquil, and happy attitude of the patient. The second case was that of a young woman who became suddenly sleepless, fretful, and irritable, and a week later had a marked tumor of the thyroid, with no other evidence of hyperthyroidism. Operation was at once performed, and the whole of the left lobe removed. The patient was well for one year, at the end of which there returned intense nervousness, and many of the classical symptoms of Graves' disease with massive enlargement of the remaining lobes of the gland. After two months of futile medical treatment, a second operation was performed under great difficulties on account of the vascular cicatricial tissue from the former operation, and the pyramidal lobe and half of the right lobe were removed. In spite of every reasonable operative precaution to avoid increasing the hyperthyroidism, this developed immediately after the patient was put to bed, with intense and prolonged nausea and vomiting, excessive irritability and apprehension, and at the end of twelve hours, with rise of pulse to 140, embarrassed, intermittent, and irregular heart action, and the supervention of cardiac dilatation. This was a picture of extreme and grave thyroid poisoning. The patient died thirty-six hours after the operation.

Hysteria—With Autopsy.—W. B. Woodbury and C. Reed report the case of a colored girl in whom hysteria manifested itself chiefly by increased and frequent micturition. The patient died from pneumothorax, which was revealed at autopsy together with evidences of acute pleurisy with effusion, chronic tuberculous pleurisy, chronic

abscess of the lung with rupture into the pleural cavity, tuberculous pneumonia and bronchitis, atelectasis, and organizing pneumonia.

Medical Photography.—N. T. Beers states that it is difficult to conceive of any branch of science in which photography is of more real service than medicine, and it is rather surprising to note how few of our profession take serious advantage of this most valuable means of record. Radiographers, microscopists, and dermatologists long since found it an indispensable adjunct in their work, and many of our foremost workers in these lines have, of necessity, become expert photographers. In years past our medical journals contained but few illustrations and these usually were woodcuts from photographs or line engravings from crude drawings in pen and ink. At their very best they excited but little interest mainly through their lack of truthful reproduction. But to-day, with the various processes of photography reduced to simple rules of thumb, the medical writer has no valid excuse for not illustrating such articles in which pictures would serve to elucidate the text. With the publisher, good photographs are always acceptable, and many a poorly written article is saved by the photographs which accompany it. The author encourages the physician to make his own photographs, and describes the various procedures necessary, from the purchase of the camera to the finishing of the picture.

Radiograms of Digestive Tract.—L. G. Cole and M. Einhorn state that the disadvantages of the bismuth method were the possibility of toxic symptoms from the large amount of bismuth administered, and that frequently a shadow was obtained that prevented one from recognizing some thickening which produces a shadow by itself. To obviate the latter difficulty they found that inflation by air enabled one to recognize tumors in earlier stages than by the other methods. This was accomplished by inserting a tube in the stomach or colon and injecting air with a Politzer bulb. They describe the technique of this method and state that while it is not able to replace the old and well established bismuth method, it will find a place in conjunction with it, or when the other cannot be applied.

Intranasal Sarcoma.—R. B. Scarlett reports a case of this condition, and states that it is usually a single tumor, of rapid growth, soft, dark red in color, and showing a great tendency to bleed on the slightest touch, sometimes resulting in severe hemorrhage, and that it also manifests a tendency to recur on removal.

Pearl-shaped Bone Formation in the Mastoid Process.—E. Amberg describes a case of the finding of a peculiar and unique pearlike bone formation, about twice the size of the head of the hammer, in the diploetic mastoid process.

The Doctor's Duty in Tuberculosis.—J. Girdwood states that in this disease the physician's responsibility is threefold: to the patient, to society, and to the State. In the first instance, early diagnosis is necessary, and endeavor should be made to convince the patient that he should enter a sanatorium for treatment. In the second instance, the physician's responsibility may be summed up in one word, *prevention*. In the third instance, the physician must fulfill the requirements of the law by registration of all cases and by instituting certain measures of protection.

Inversion of Puerperal Uterus.—R. E. Davison states that Hirst's operation for this condition is the best operation to-day and can be executed easily, rapidly, and successfully. It consists in slitting the cervix in the median line posteriorly, the incision being carried higher on the internal than on the external surface, the ring muscle being almost if not completely severed without opening the peritoneal cavity. With comparatively light pressure with one finger tip on the lower uterine segment just above the upper angle of the wound he easily reinverted the uterus.

Retroversion of the Uterus.—E. A. Schumann states that Baldy has formulatd two general rules of the highest importance in approaching the question of the form of operation in such cases. The first is that retrodisplacements of the uterus are mostly coincident with other lesions, and where such is the case, the symptoms almost universally come from the associated disease. The treatment of retrodisplacement is a misnomer. It should be the treatment of the conditions in connection with which retrodisplacements of the uterus occur as an accident. There are certain operative factors that must obtain if an ideal result is to be secured. These, in part, are as follows: 1. The operation must bring the uterus forward and maintain it in this position. 2. It must offer facilities for dealing with adhesions and other intraabdominal complications. 3. It must attain the desired result with a minimum amount of multilation. 4. The uterus must remain a pelvic organ and not be dragged high up into the abdomen. 5. Such motility and power of equal and general expansion must be maintained that subsequent gestation is not impeded. 6. The generally prolapsed and enlarged ovaries should be elevated, together with the uterus.

Epidemics Among Alaska Indians.—S. A. Savitz states that measles was the first of the infectious diseases which unmercifully attacked the Indians in Alaska. About 33 per cent. of those who were attacked succumbed. Pneumonia was the most frequent complication, which was probably largely due to the practice of bathing in cold water upon the appearance of the eruption. In 1872 smallpox broke out and proved very fatal. This disease is traced to the Spaniards, who conveyed it to America in the sixteenth century. During this epidemic the vast majority succumbed before the eruptive stage. In 1876 there broke out an epidemic of influenza which invaded all the coast cities with great rapidity. This disease existed among them long before civilization made its entrance. The Indian race has been dying out steadily and rapidly and the few that are left are wasting away before the ravages of tuberculosis. There is evidence that this disease existed among the Indians before the advent of the white man; they used the bark of hemlock to control pulmonary hemorrhage for a long time. The power of resistance, not only to tuberculosis, but also to other diseases, decreased in proportion to their adoption of civilized customs.

Alcohol and Legal Medicine.—M. Keschner describes the noxious effects of alcohol upon the organism, the various degrees of drunkenness, the symptoms and treatment of delirium tremens, alcoholic convulsions, and alcoholic insanity, and discusses the relation of alcohol to legal medicine under the headings of crime, contracts, torts, wills, and insurance.

Campaign Against Malaria.—G. E. Henson states that in the Southern States during the past decade there has been little decrease in the morbidity from this disease, and contrasts the results obtained by an intelligent and active

campaign against its ravages in other countries. In Italy, in the course of five years there had been a reduction in the mortality of 65 per cent. The prophylactic measures and methods to stamp out the infection, may be classed as follows: First, the education of the public that the mosquito is the etiological factor in malaria, also as to its habits, and how to protect against it. Second, the destruction of the mosquito in its larval and adult stages. Third, the prevention of the development of the plasmodium in man. Fourth, the entire eradication of the parasite from an individual, in so far as possible. The prophylactic value of quinine is commented upon; in Italy this drug is sold by the government at a minimum price, and given away free to those who cannot afford to pay for it.

Bacteriology of Acute Respiratory Infections in Children.—L. Emmett Holt presents this study, which is reported in the MEDICAL RECORD, Vol. 77, page 783.

The Negro as a Health Problem.—H. M. Folkes asserts that the colored race, before the abolition of slavery, showed a higher standard of health among the children than has ever been maintained since their emancipation. At present, the conditions are much less favorable, and the exemption from infectious diseases observed in the children of intelligent white people is seldom seen in the negro. Those diseases to which the negroes are more immune than whites occur in greater frequency among the mixed bloods, in proportions according to the dilution. Negroes of all shades are especially susceptible to tuberculosis and measles, but, in an experience of nearly twenty years, he cannot recall a case of scarlet fever, diphtheria, mumps, or tonsillitis among black negroes. He recognizes a great improvement both among whites and negroes during the last ten years, but one of the gravest problems confronting the whites of the South is to prevent tuberculosis and venereal disease among the colored population.

Hemiplegia Following Acute Infections.—W. A. Jones and A. S. Hamilton report several cases of paralysis of central origin following diphtheria, pneumonia, and conditions causing encephalitis of rather obscure nature. Central paralysis from diphtheria has been little recognized in the textbooks, though the deleterious effects on the peripheral nerves have been long recognized. In the two cases here reported, there was undoubtedly a central lesion in each, though in one it is possible that there was also a peripheral lesion. Whether the cause in these cases of hemiplegia following diphtheria was acute encephalitis or thrombosis and hemorrhage, it is difficult to determine, though the symptoms in both cases suggest encephalitis rather than one of the acutely acting vascular conditions. Paralysis of either central or peripheral origin in pneumonia is rare, and though there is no apparent reason why a central paralysis in pneumonia might not be due to true encephalitis, the authors have not found any case reported in the literature except in connection with meningitis. The last two cases reported seem to justify the diagnosis of encephalitis, though post-mortems were not made.

Tuberculosis in Milk.—F. O. Tonney gives an account of the work done by the Chicago Department of Health in the examination of market milk for tuberculosis germs. Guinea pigs were used for the tests. After inoculation they were kept in clean cages and were observed for three months. Of 112 specimens of milk, 8.9 per cent. proved tuberculous. Comparing this with observations made in other cities and combining their figures with these, he finds the incidence of tubercle bacilli in the milk supplies to be about 8.3 per cent. The milk-produced diseases of children are, he thinks, first in order, the diarrheal diseases responsible for about one-third of the deaths among children under two years in our large cities; second, is typhoid fever; third, is tuberculosis; fourth, is scarlet fever; fifth, is diphtheria; and sixth, a group of miscellaneous disorders not particularly important in this country, such as cholera and foot-and-mouth disease. He thinks that these may be largely eradicated by strict observation of sanitary rules in the production and handling of milk.

Alveolar Abscess.—S. L. McCurdy believes that dentists should realize the seriousness of the most frequent operation they perform, namely, that of devitalizing and extracting pulp, since infection and serious bone destruction arise from this source. The symptoms, especially if complicated with syphilis, may be very uncomfortable. Destruction of the bony floor of the antrum does not necessarily mean perforation of the membranous floor or infection. An alveolar fistula leading into a cavity containing a considerable portion of the tooth requires extraction of this tooth before recovery can be obtained. Persistent headaches and general reduction of health are frequently caused by very insidious alveolar abscess. He thinks it desirable, in case of necrosis of the mandible calling for removal of bone, to establish drainage through the chin and approximate the gingival margins with sutures so as to shut off the pus cavity from the mouth. Nasooral fistula, which sometimes occurs, especially in syphilitics, can be cured after due constitutional treatment by a membranous flap from the roof of the mouth. Tincture of iodin is recommended in all suppurative conditions of the mouth as a disinfectant.

Anesthesia in Head Surgery.—J. E. Lumbard recommends the use of glass tubes connected with rubber tubes to the mechanism supplying the anesthetic vapor in head surgery. These are to be inserted into the nostrils as in the methods of Pynchon and Blakely, which they are intended to supersede. He introduces anesthesia in the usual way, and then introduces the glass tips into the nose. For convenience they may be held in position by adhesive plaster. He claims for the tubes a safer and easier introduction than is possible with the rubber tubes heretofore employed, and their successful use is not interfered with by a deformed septum or exostosis. They do not cause nasal hemorrhage and cannot become obstructed with blood or mucus. They remain in position much better than rubber tubes and they are easier to clean and sterilize.

Middle Meningeal Hemorrhage with Hemiplegia.—L. L. Smith reports a case of fissure fracture of the skull, without depression of bone or signs of compression, causing a supradural hemorrhage from the middle meningeal artery and total right hemiplegia. The left facial nerve was apparently somewhat involved by the extension of the clot. The removal and cleansing out of the clot relieved the hemiplegia, though the muscles were still slightly weaker for about five days. The patient was at work a week after his discharge from the hospital. The rarity of an extradural hemorrhage from the middle meningeal artery causing hemiplegia makes this case of some interest.

Actinomycosis.—F. T. Lord reports finding the pres-

ence of actinomycetes in the contents of carious teeth and the tonsillar crypts of patients without actinomycosis.

Complement Fixation with an Antigenic Crystal from Luetic Liver.—C. F. Craig reports the discovery of a crystal formed in a strongly antigenic extract of luetic liver which apparently possessed similar antigenic properties.

Internal Ear Complications of Middle Ear Diseases.—J. Holinger gives a general survey of the pathology and prognosis of inflammations of the internal ear. He discusses the subject under the following classification: I. Serous labyrinthitis. II. Labyrinthitis in connection with acute otitis media, including scarlet fever, diphtheria, and otitis, leading to formation of sequestrum. III. Chronic labyrinthitis in consequence of cholesteatoma. A. Circumscribed labyrinthitis. B. General labyrinthitis, caries, necrosis. IV. Tuberculous labyrinthitis.

Labyrinthitis.—J. R. Fletcher states that it is important to distinguish between the suppurative and the serous and hyperemic forms. In the former, the cochlear symptoms are negative and hearing is completely lost, but in the serous and hyperemic forms some hearing remains and spontaneous recovery occurs. In latent labyrinthitis the history is of most importance, as the patients must have had previous attacks of vertigo and nystagmus, either total deafness exists or only a remnant of hearing is found. There are no characteristic spontaneous symptoms. Perilabyrinthitis, or inflammation of the cellular bone tissue around the labyrinth is most frequently associated with acute suppurative otitis media or with acute exacerbations of chronic disease. The mastoid is always, and probably first, involved, and some systemic diseases, especially diabetes, predispose to it. When the process is acute it is hyperemic, as is shown by rapid recovery of hearing following mastoid operation. In the serous type recovery is slow, depending largely on the drainage of perilabyrinthine spaces. If suppurative, sequestration is apt to follow. The early symptoms are those of mastoditis with gradual onset, of diffuse endolabyrinthitis, recurrent deafness, pain on pressure over the upper part of the mastoid process, frequent facial paralysis, and the Weber test in the diseased ear. The negative symptoms are absence of the fistula symptom or vertigo attacks and infrequence of intracranial complications. The importance of diagnosis relates mainly to the question of operation.

Vertigo.—G. E. Davis states that the internal ears are the special sense organs of equilibrium. By them we recognize (orientation) and maintain our relations to space (equilibration). The visual sense organs and the kinesthetic sense organs (the muscles, etc.), are accessory sense organs of equilibrium and are coordinated with the internal ears through the mediation of the cerebellum. The special sense organs, the two internal ears, one on each side, are normally symmetrical in structure and function, and anything, whether physiological, experimental, or pathological, which innervates, stimulates, or irritates one of these twin organs more than the other, or accomplishes the same thing through enervation, depression, or destruction of one in excess of the other, in that measure tends to or creates proportionally disturbance of their joint function, equilibration. If this disturbance is sufficiently marked or intense there result nystagmus and vertigo.

Foibles in Specialism.—C. F. Wahrer comments upon the absurd advice often given by specialists to poor patients, upon unnecessary details given in reports of cases, the danger of too close application to specialism, and upon the fact that the modern textbook is too padded for practical purposes.

Colloid Carcinoma of the Skin.—A. Bamberger reports this case because of its rare occurrence, and because it emphasizes the importance of laboratory work in cases of obscure diagnosis.

Joint Tuberculosis and Tuberculous Sinuses.—L. W. Ely states that in numerous articles in the past he called attention to the importance of avoiding secondary infection of the walls of tuberculous sinuses and abscesses by the germs of suppuration, and pointed out the danger the patient incurs if this secondary infection take place. In this he followed the teachings of others and his own experience, gathered in treating many cases of joint tuberculosis. On the other hand, the custom of opening, scraping, and packing tuberculous abscesses is still widespread, and those who practise it do so either from ignorance or because their experience teaches them that it is correct. A very suggestive case of tarsal tuberculosis recently furnished him with additional evidence of the truth of these contentions.

Malignant Disease of the Nasal Passages: Its Diagnosis, Pathology, and Treatment.—W. Stuart-Low states that malignant disease of the nose may begin outside the nose (extrinsic origin); in its early stages the disease may appear in unusual and obscure forms; and if operated upon in time is often readily amenable to cure. The extrinsic forms are most apt to be confounded with cysts of the antrum (mucocele) and dental cysts. Sarcoma is the form of growth most frequently met with in the interior of the nose. Nasal polypi may become sarcomatous. Carcinomata consisting of squamous cells originate usually in the ethmoid region. Those inheriting thin mucous membranes are most liable to cancer. Carcinoma is more common in the antrum than in the frontal sinus. The author states in conclusion that there are some practical lessons to be learned from a study of this subject: 1. Pain is not to be relied upon as an indication of malignant disease in the nose. 2. Increasing and persistent stuffiness, especially if unilateral, is an important point as regards diagnosis. 3. Recurring and increasingly severe hemorrhage, especially if unilateral, is always a suspicious symptom. 4. A combination of hemorrhage and increasing stuffiness is often a serious indication of new growth existing. 5. The making of an early diagnosis is of great importance. 6. It is imperative to make a thorough and systematic examination in all obscure cases of nasal disease, and to remove early a piece of any obstruction in the nasal passages for a pathological report. 7. It is of great importance when there is malignant disease to operate as soon as possible after a diagnosis has been made to secure a successful removal. 8. It is advisable to adopt the canine-fossa route in operating for the extirpation of intranasal tumors. 9. Innocent and malignant polypi are likely to coexist.

The Essential Cause of Gastric and Duodenal Ulcer.—C. M. Moullin states that the starting point of what is commonly known as gastric or duodenal ulcer is the digestive destruction of more or less of the wall in one particular spot. Tissues that produce gastric juice or are normally bathed in it are not affected as long as they are healthy and uninjured, owing to an immunity acquired in the course of development. This immunity is not shared by the submucous and muscular coats. Direct local causes of gastric ulcer are direct violence, the wearing of ill-fitting

stays by women of the domestic class, and swallowing corrosive poison. One of the best known local causes is embolism, the evidence of whose presence is seen in the flame-shaped patches of hemorrhagic exudation. Embolism is the immediate cause of the gastric and duodenal ulcers that occasionally develop after injuries and operations, especially those involving bones, and that occur in the course of acute infectious disorders and in septic infection and intoxication. The presence of septic poisons circulating in the blood, possibly excreted in part by the gastric mucous membrane, cannot but have a strongly predisposing effect. The superficial erosions, as distinguished from genuine ulcers, are probably all caused this way. Arterial degeneration has been described as occurring in recent acute cases, and in chronic cases is so common as to be the rule. Thrombosis can act as a cause. The gastric and duodenal ulcers occasionally found after injuries to the brain and spinal cord, and those caused by subphrenic section of the vagi, and by injuries of the splanchnics and of the cœliac plexus, are also the result of local vascular lesions. The same is true of ulcers occurring in heart disease other than endocarditis, and those that are occasionally found in Bright's disease, advanced jaundice, hepatic cirrhosis. In the vast majority of cases these local agencies do little more than determine the site. The essential factor is the morbid condition of the mucous membrane, consisting in an extreme degree of congestion and edema, which precedes ulceration and often leads to it. Hematemesis is caused as frequently by minute lesions in the intensely congested mucous membrane as by the giving way of an artery on the floor of an ulcer. The pain of ulcer owes its origin far more to the general morbid condition of the mucous membrane than to the presence of a gastric ulcer. The immediate source of the pain is the spasmodic cramp of the muscles around the antrum and the pylorus, which is started by the extreme sensitiveness of the mucous membrane, intensified by inflammation spreading from the erosions and abrasions that are so often present. The exquisitely hypersensitive and hyperemic condition of the mucous membrane is the cause of pylorospasm with the consequences it entails: retention of hydrochloric acid (so-called hyperchlorhydria) and impaired motility, excessive secretion, hemorrhages, erosions, and in many instances ulcers are all due to it. The most important and most frequent cause that gives rise to this condition of the mucous membrane is general septic poisoning. A local septic poisoning is caused by the persistent swallowing of septic toxins manufactured in the mouth and throat, chiefly in the presence of carious teeth. While gastric ulcer is exceedingly common in this class of cases, duodenal ulcer is very rare, which is explained by the fact that the action of septic poisoning which is swallowed is local only, while if the septic poisoning acts through the medium of the circulation it affects both stomach and duodenum. In young women the effect of this chronic septic poisoning is intensified by the habit of swallowing quantities of vinegar. Certain substances known as gastrotoxins when injected into the peritoneal cavity cause patches of necrosis in the mucous membrane of the stomach. Other indirect causes are unsuitable foods, irregular meals, overeating after periods of fasting, exposure to colds, cholelithiasis, chronic appendicitis, chronic gastric or duodenal ulcer (which though itself a consequence, is no less able to act as a cause), pylorospasm, and movable kidney. The actual starting point of an acute gastric ulcer is nearly always one of the enormously enlarged and inflamed lymphoid follicles.

The Physique of the Phthisical.—H. de C. Woodcock states that the phthisical soft palate is of a pearly bluish-white tint and is covered with a somewhat mucoid moisture. It differs from the chlorotic palate. It is to be ranked with the temperature and pulse as an important sign. Another important sign is the fatigue reaction, which consists in a rapid rise of temperature caused by fatigue, which, if occurring in the morning, is followed by a slow descent lasting until, and merging in, the usual evening rise. Hyperextension of the fingers on the metacarpals or of the terminal on the penultimate phalanx is a sign commonly found in the cases of people in advanced or rapidly advancing phthisis. Philip's glands, which are enlarged deep glands just above the clavicle, are always found in phthisical children; they are frequently met with in normal children. Marked acne is hardly ever found among advanced phthisicals. Dilatation of the stomach is of common occurrence among tuberculous patients. Among the Jews the tendency is to tuberculous morbidity, not to mortality. Rapid increase in weight increases any present liability to hemoptysis.

Symptom-Complex in Ruptured Abdominal Hydatid.—J. E. Barling and D. A. Welsh refer to six cases of hydatid disease complicated by rupture or leakage of the cyst into the peritoneal cavity. In five of the cases the cysts were in the liver, in the remaining one in the spleen. They presented the following symptom-complex: (1) eosinophilia, (2) peritonitis with effusion, and (3) urticaria.

Clinical Surgery in Japan.—Y. Takaki concludes his contribution on this subject in discussing his experience during the past four years in the treatment of acute appendicitis, calling attention especially to the danger signs in the early stage.

Henoch's Purpura with Enteric Intussusception.—H. B. Robinson reports a case of this condition in which hemorrhage into the bowel wall caused paralysis of that segment, and hence intussusception. The beginning of the marked blood staining was in the region of the apex of the intussusception.

Electric Treatment of Prostatic Obstruction.—J. S. Bolton describes his method of relieving the symptoms of prostatic obstruction by the passing of an electrode into the rectum and administering high-frequency currents. This treatment may make the patient comfortable, may remove the necessity for catheter interference, and restore his hope for the future.

A Reminder of the Battle of Omdurman.—J. B. Christopherson gives an account of the removal of half a shrapnel bullet which had remained embedded in the leg of an Arab for eleven years after the battle.

German Measles.—C. Beards and W. L. Goldie discuss the etiology and diagnosis of this disease. The principal conditions from which it has to be diagnosed are prodromal rashes, other exanthems, influenza and diphtheria with eruption, specific rashes, drug and toxic rashes, and skin diseases.

Use of Stovaine in Shock.—G. Thom states that in combating the shock attendant upon injuries of the lower extremities with stovaine immediate improvement after injection is noticeable—pain and restlessness disappear, the pulse improves rapidly, the color returns, and the patient's distress diminishes. The injection is made as for spinal analgesia.

The Ownership of Medical Prescriptions.—H. W. Gadd discusses the legal aspects of this question, stating that the most feasible solution of the problem would appear to be the treatment of the question as one of etiquette between physician and pharmacist.

Ancient Humorism and Modern Humorism. C. Richet
Absence of the Fallopian Tubes and Menstruation. W. G. Spencer and A. Doran.
The Quickening Spirit. L. Williams.

Ancient Humorism and Modern Humorism.—Charles Richet states that the physiological concepts of to-day

might very well be expressed by a very old word, now perhaps a trifle out of date, "humorism." It is by the chemical evolution of the substances contained in the plasmatic liquids that life is constituted. According to the ancients, life depended upon the humors: blood, yellow bile, black bile, and phlegm. With the Italian anatomists of the Renaissance humorism was replaced by mechanism, and with the coming of Lavoisier, chemistry became the handmaid of medicine and physiology. Lavoisier demonstrated that life is a chemical phenomenon. The succeeding era was the one in which the micrographers appeared to draw physiology towards histology, histogenesis, and cellular morphology. But physiologists had not allowed themselves to be misled by the mirage of the microscope; they pinned their faith on chemical and physical experimentation, not on morphology; but medicine was not as wise as physiology, for it believed that microscopic anatomy was going to clear up everything. Despite the genius of Virchow the history of cellular pathology had ended in failure. The experimental methods of Pasteur, Koch, and Ehrlich have opened up those marvelous discoveries by means of which every branch of medicine has been regenerated—etiology, pathogeny, hygiene, therapeutics. It was even necessary, in the study of bacteria, to come back to biologicochemical analysis, which is the essence of humorism. With the discovery by Roux of toxins in the blood, and with the discovery later that the blood contains substances capable of producing immunity, there was begun the universal study of the chemical functions of the blood, which is humorism in the strictest sense of the word. One of the first laws of modern humorism is that the quantities of substances which come into play in physiological reactions are often in such minute proportions that they may be called imponderable. The study of anaphylaxis has shown that the injection of certain albuminoid substances may produce this condition, which is the opposite of protection, or the greater sensitizing of the organism toward the toxic substances, even when these are administered in a dose of a thousand-millionth part of a gram. The second law of humorism is that the activity of a liquid results from the conflict of two substances which, isolated, are inactive. Thus anaphylaxis is due to the combined action of two substances which are powerless when apart, antigen and toxogenin. Similarly emulsin and amygdalin are separately harmless, but together they produce the poison, hydrocyanic acid. In the cells the toxins and ferments do not exist as such, but as protoxins and proferments, substances possessing hardly any toxic or fermentative action, but which are so unstable as to be transformed into real toxins and real ferments under very slight chemical influences, weaker than the ordinary laboratory reagents. If this instability of chemical substances be given its real name, it is irritability. Thus, the writer maintains, the irritability which rules the functions of the nervous system is in itself a humoral phenomenon.

Absence of Fallopian Tubes.—W. G. Spencer and A. Doran report a case of this condition, with absence of menstruation, in which there had been recurring monthly attacks of peritonitis, and in which relief followed an operation joining the ovarian pouches with the uterine cavity.

The Quickening Spirit.—L. Williams discerns in the trend of present-day medical thought a movement which is destined to occupy a great deal of time and interest in the immediate future, namely, a movement to recognize the influence that mind exercises over matter. He agrees with Osler, that "the profession is now riding on the top of a cardiovascular wave," and believes that the physical ills that beset emotional patients are due primarily to circulatory causes. One can no longer neglect the aid of the mind as a therapeutic agent.

Strychnine Poisoning and Intratracheal Insufflation.—Shaklee and Meltzer have sought to improve on the old curare treatment of strychnine poisoning by using Meltzer's recently devised method of intratracheal insufflation. The animals were etherized and made fast to the table. The etherization was then continued through the tracheal tube. In order to cause elimination of some of the ether, the jugular vein was then opened, and pure air forced into the trachea. In the jugular vein opening strychnine was injected. Tetanoid spasms developed promptly, and then the curare was injected. The heart beat of the animal was the only sign of life. Artificial respiration was instituted to conserve life. At this stage a very little more strychnine would have killed, while artificial respiration and the injection of curare would prove antidotal to a certain degree. A dose of strychnine (0.4 mg. per kilo) could not be antidoted and was therefore lethal. Cases of strychnine poisoning on a border line could be offset by combined insufflation of air and injection of curare. This combination could be shown, by varying the experiments, to antidote part of the strychnine syndrome, and this might or might not prove life-saving.

Pathology of Acute Articular Rheumatism.—Mosler and Valentin discuss the large number of cases which pass annually through the Rudolf Virchow Hospital. The statistics in course of accumulation show much that is of interest, but not much that leads to fixed principles. In a series of 135 patients there were 3 deaths, not necessarily dependent on the natural tendency of the disease. No less than 118 patients were discharged cured; by cure here is meant not only complete subsidence of symptoms, but a few cases in which physical defects were well compensated and no treatment required. There were 19 cases discharged improved; all of these requiring continuous outpatient treatment, from active persistence of certain symptoms. Two cases were set down as discharged uncured, because they disappeared from medical observation while still presenting active lesions.

Examination of the Stomach with Bismuth Capsules.—An excellent article of Max Cohn contains much information which, however, is poorly arranged for abstraction. The relation of a single case may serve to convey the author's views and method: A girl, aged 24, delicate, admitted for anemia, was given black tea early in the morning. Several hours later she received a "sinking capsule," accompanied by one-half pound of roast veal and later a "floating capsule." She was then radiographed. The sinking capsule lay at the lowest point of the stomach, in the food mass. Two hours later both the bismuth capsules were seen at the lower pole of the stomach; later they dissolved in the duodenum. This neat result is however not so readily explained. The digestive mixture in the stomach may vary with the case. The part played by mobility also varies. Authors generally concede that a stratification of stomach-contents may occur, and that this depends largely on the diet. Thus in flesh feeding we see no stratification, while in leguminous feeding the gastric juice and digesting substance form layers. In achylia gastrica we should expect particular findings. Progress along these lines will be impeded by the interdependence of a large number of factors.

Infantile Paralysis in Russia.—Jogichess, of a children's hospital in St. Petersburg, states that this affection which has recently begun to flourish in middle and western Europe, appeared almost simultaneously in St. Petersburg, he having during the fall and winter of 1909-10 some 29 patients under his treatment. His service at the Prince

Oldenburg Hospital for Children dated back to 1900, and sporadic cases occurred during the subsequent years. In 1905 the accumulation of cases was sufficient to suggest epidemicity, some 18 cases having been admitted during and after July. The affection then sank to the sporadic type until the fall of 1909. It appears, therefore, that there is an accumulation of this disease at periodical intervals. Opinions differ as to whether cumulation implies epidemicity. Yet these affections of small incidence, like infantile paralysis and cerebrospinal meningitis, appear to follow the same general law as diseases of large incidence, such as measles and scarlatina. Every half a dozen years or so we see in both classes an accumulation of cases which may or may not be looked on as epidemic. This cumulative element naturally takes a disease quite out of the realm of pestiferous and is opposed with difficulty by hygiene. It complicates the nosology of disease; for example, influenza is of a pestlike and pandemic character, and yet there are influenza years which only exhibit normal cumulative incidence. Such topics are naturally freely covered by epidemiologists, even those of ancient date. The author concludes by stating that his cases come rather from the outlying country than from the metropolis.

How to Enhance the Strength of Local Anesthetics.—Gros writes briefly on a subject which has already received considerable attention. If chlorides of the various narcotics are combined with sodium carbonate in solution, the resulting alkaline solution acts more powerfully than the original acid chloride fluid. This may best be shown by an example. If we wish to use any of the synthetic anesthetics to anesthetize a nerve trunk, where a small area of tissue only is to be affected, a concentrated or acid chloride solution cannot be neutralized chemically by the alkaline fluids in the neighborhood. Now the injection of a bicarbonate solution of the anesthetic into the alkaline tissues gives the anesthetic basic substance a higher concentration than when an acid chloride solution is used; for chemical neutralization then becomes unnecessary, and the specific action is then more freely exercised.

Case of Intermittent Limp.—Fischer takes up this subject as left by Goldflam. His article is a simple case report with comments, which are peculiarly controversial in character, the author directly opposing both Goldflam and Erb. The author's case differs from most of those recorded in that it had already flatfoot with all its accompaniments and consequences; so that the disease may be regarded as a complex. The two affections have been held to be due to the same mechanism. In this case both angiosclerosis and flatfoot were markedly in evidence. The latter affection derived no benefit from the usual remedies. Patient was a very heavy smoker and this fact, according to Erb, would have sufficed to cause arteriosclerosis. The most remarkable feature of the case was that ischemia of the foot, due presumably to arterial disease, developed later into a hyperemia. This sudden reversal may, perhaps, have been due to free use of amyl nitrite as a vasodilator. The ischemic member was also subjected to more or less mechanotherapy—evidently very little, as the mere shaking of the foot or knocking it against the other. The amyl nitrite seems to have been the main resource. None of the remedies approved by Erb or Goldflam gave any relief. It is admitted by the author that his case is unique, and it further appears that we may not as yet have obtained any sure hold on the condition known as intermittent limp.

Deutsche medizinische Wochenschrift.

September 22, 1910.

Renal Dropsy.—Richter sums up our knowledge to date of this clinical condition in certain aphorisms as follows: Three factors are always involved, viz., (*a*) an anatomical element which must necessarily involve a functional element, through which the elimination of water and salts is interfered with; including (*b*) a special retention of water and (*c*) an injury to the vascular wall which enhances its permeability. These factors are commonly admitted to exist, but by no means are they equally represented in a given case. The primary cause must be injury to the kidney itself and the vessels. Retention of saline matter alone can lead to retention of water, not necessarily to dropsy. This water retention leads to dropsy, but is not dropsy in itself. The two remain, at least in adults, in sharp differentiation. In the nursling there is no abrupt distinction between preedema and edema itself. The vascular system of the nursling exhibits a greater lability. Senator has shown that almost all effusions in the nursling are free from cell content.

Nitrous Acid Poisoning.—Savels refers to the extreme infrequency of this kind of poisoning, especially of late years; so that we are in some danger of forgetting its characteristics. He has known of eight cases, and sums the matter up as follows: The symptoms are manifold, but may be comprised as follows: There is a high degree of dyspnea, cyanosis, pulmonary edema, and pneumonia, together with cardiac weakness and disorder of the sensorium, amounting to delirium. It has been assumed that the inhalation of nitrous vapor can affect the organism in three ways, viz., (1) by direct injury of the lung cell and bronchioles; (2) by reducing the alkalies of the blood, and (3) by certain affections of the central nervous system, which may be looked upon either as toxic in nature or as a direct result of toxic blood. The treatment is about as follows: The patient is bled and then infused with saline solution; he is then allowed to drink freely of alkaline water. Inhalation of dilute ammonia is practised, as is also inhalation of oxygen by Roberts' method. Hematinics may be required according to indications. This therapy is reinforced or superseded by the use of from 3 to 5 drops chloroform, dissolved in water, every ten minutes.

Permanent Preparations of Urine Sediments.—Skutetzky, a military surgeon of Prague affiliations, takes up a subject of generation-old interest. It is, of course, very easy to preserve an ultra-acid or ultra-alkaline sediment as it stands. Of much more value is the preservation of a sediment in which the reactions cut no particular figure. The author's method deals naturally with exceptional cases. A mixture of sediment is obtained in a watch glass cover, which from the first contains only matter free from gross chemical alterations. The chief subject involved is a preservative, which is made up of linen cloth and distilled water, in the proportion of 1 to 2. The gelatin of the former combines with the sediment, and from the dark background of the former the formed elements of the sediment stand out clearly. Hyalin casts, otherwise not noticeable, stand out brilliantly. The particular linen fabric employed is the so-called "lineol, No. 290," of Gunther and Wagner. The method not only serves to bring out latent sediment, but also preserves it.

Removal of the Frontal Bone for Septic Osteomyelitis.—C. J. Symonds reports a case in which the infection followed chronic suppuration of both frontal sinuses, and existed before operation. In a series of operations the frontal bone was removed, together with a part of the sphenoid, the roof of the right orbit and its inner wall, and the orbital ridge. On the left side part of the orbital ridge was left. The case was shown as an example of a rare complication, and as a recovery from a grave condition of infection. The other point of interest was the reconstruction of the greater part of the frontal bone and the consequent restoration of the forehead. On the left side the frontal sinus had been operated upon by the method of Watson Williams with no perceptible scar.—*Royal Society of Medicine.*

Book Reviews.

THE DISEASES OF CHILDREN. By JAMES FREDERIC GOODHART, M.D., LL.D. (Aberd.), F.R.C.P., Consulting Physician to the Evelina Hospital for Sick Children; Consulting Physician to Guy's Hospital; late Demonstrator of Morbid Anatomy and Lecturer on Pathology in its Medical School. Ninth Edition, edited by GEORGE FREDERIC STILL, M.A., M.D., F.R.C.P., Professor of Diseases of Children, King's College, London; Physician for Diseases of Children, King's College Hospital; Physician to Out-Patients, the Hospital for Sick Children, Great Ormond Street. Philadelphia: P. Blakiston's Son & Co., 1910.

THE publication of a ninth edition of this well known work is justified by its popularity, and has been rendered necessary by the numerous recent advances, in some cases revolutionary changes, in the science and art of pediatrics. Both of the authors have made a thorough overhauling of the book, have added a good deal of new material, and for the first time have inserted a few illustrations. They have succeeded in presenting a readable and at the same time complete textbook on diseases of children, valuable both to the student and to the practitioner. Considerable space has been devoted to treatment. The citation of illustrative cases is a happy didactic feature. The subject of infant feeding is covered thoroughly, but without the overelaborate complexity of the average treatise. Many readers will not agree with the statement that barley-water has a distinct laxative effect. Nor will American pediatrists concur in the doubt that intubation will ultimately take rank as a generally serviceable measure in diphtheria. Full credit is given to the efficacy of Flexner's serum in the treatment of epidemic cerebrospinal meningitis. Admirable features of this work are the omission of extended description of these features of disease that are not specially applicable to childhood, and the appendix containing numerous therapeutic formulæ.

DIE AMBULANTE BEHANDLUNG DER UNTERSCHENKELGESCHWÜRE. Dr. Jessner's dermatologische Vorträge für Praktiker. Heft 7. Vierte Auflage. Würzburg: (Curt Kabitzsch) A. Stuber's Verlag, 1910.

DR. JESSNER has made his name familiar in the medical literature of Germany by the authorship of numerous small monographs on dermatological and kindred subjects. The present booklet considers the etiology and the treatment of chronic leg ulcers, that so commonly accompany varicose veins. It forms a trustworthy little guide in this special subject, and should prove very useful to doctors in charge of minor surgery departments of dispensaries, that are usually overrun by patients suffering from chronic leg ulcers.

A TEXT-BOOK OF PATHOLOGY FOR PRACTITIONERS AND STUDENTS. By JOSEPH MCFARLAND, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Philadelphia General Hospital and to the Medico-Chirurgical Hospital, Philadelphia; Director of the Laboratories of the Henry Phipps Institute, Philadelphia; Fellow of the College of Physicians, etc. Second edition, thoroughly revised. With 437 illustrations, a number in colors. Philadelphia and London: W. B. Saunders Company, 1910.

THE second edition of this work on pathology appears about six years after the first. We find the new book but little larger than its predecessor. The chief additions are a short chapter on regenerative tissue changes, and a few illustrations. Other changes noticed are the addition of a short section on senescence; the section on the parasite theory of the origin of tumors has been rewritten; the classification of tumors has been revised; and part of the chapter on immunity has been altered. It will be noted that the changes are few, and the revision but slight. Perhaps this is explained by a sentence in the preface. "To a busy man the revision of a book of this size is a task more easily neglected than accomplished." It is a pity that the author has selected "the easier way," for the book is a good one, it contains a great deal of useful material, and it is well arranged. But it is handicapped by the size of the type; the larger of the two types used is too small, and the smaller is ruinous to the eyesight. Among the slips which should have been corrected are the following: Condyloma late, also condyloma lata (on the same page it also occurs correctly as condyloma latum), verrucæ digitata, verrucæ filiformis, nævi prominens, membrana granulosum, corda tendineæ, pemphigus exfoliativa, lupus tuberosa, lupus verrucosa, lupus nodosa, lupus hypertrophica, nævi vasculosi tuberosa, empetigo contagiosum. The occasional French expressions will also bear revision; the proper names are not above reproach; and the general style and syntax are, at times, open to criticism, even in this revised edition.

GYNECOLOGICAL DIAGNOSIS. By WALTER L. BURRAGE, A.M., M.D. (Harv.); Fellow of the American Gynecological Society; Member of the Obstetrical Society of Boston; Consulting Gynecologist to St. Elizabeth's Hospital; formerly Visiting Gynecologist to St. Elizabeth's and the Carney Hospitals; Electrotherapeutist and Surgeon to Out-Patients' Free Hospital for Women; Clinical Instructor in Gynecology Harvard University; and Instructor in Operative Gynecology in the Boston Polyclinic. With 207 text illustrations. New York and London: D. Appleton & Company, 1910.

THIS book is a valuable addition to the large number of special works on diagnosis that have appeared during the past few years. In gynecology, more than in any other branch of medicine, diagnosis presents many difficulties and pitfalls for the general practitioner. For the latter this work has been particularly designed. It is eminently practical, embodying simplicity of technique and concise statement of essentials. The rare diseases are kept in the background, and greater emphasis is placed upon the common affections usually met by the general practitioner. Differential diagnosis is thoroughly covered, particular attention is paid to the diagnosis of the diseases of the bladder and rectum, a chapter on diseases of the breast is included, as well as comprehensive chapters on the gynecological affections of infancy and childhood, and on the menopause. The illustrations are numerous, of a high order of artistic merit, and are alphabetically indexed at the beginning of the work. The author has succeeded in presenting a work of uncommon usefulness to the general practitioner.

HYGIENE AND MORALITY. A Manual for Nurses and Others, Giving an Outline of the Medical, Social, and Legal Aspects of the Venereal Diseases. By LAVINIA L. DOCK, R.N., Graduate of Bellevue Hospital Training School, Resident Member of the Nurses' Settlement, New York, Secretary of the International Council of Nurses. New York and London: G. P. Putnam's Sons. 1910.

THE purpose of this book, as the author declares, is to emphasize the social significance of the venereal diseases and the part that women should play in the war against this evil. The three sections deal respectively with the venereal diseases, prostitution, and the prevention of venereal disease. The chapters on syphilis and gonorrhea are clearly and scientifically written. In the second section are considered the control and regulation of prostitution and the white slave traffic. In discussing the prevention of venereal disease the writer states that enfranchisement of women is the first step. The book was written primarily for nurses, but with the hope that other women will find it useful. The published price is $1.25.

THE PRACTICE OF MIDWIFERY. Being the seventh edition of Dr. Galabin's Manual of Midwifery, greatly enlarged and extended. By ALFRED LEWIS GALABIN, M.A., M.D. Cantab., F.R.C.P. Lond.; late Fellow of Trinity College, Cambridge; Consulting Obstetric Physician to Guy's Hospital; late President of the Obstetrical Society of London; late Examiner in Obstetric Medicine to the Universities of Oxford, Cambridge, London, and New Zealand, and to the Royal College of Physicians and Surgeons; and GEORGE BLACKER, M.D., B.S. Lond., F.R.C.S. Eng., F.R.C.P. Lond.; Fellow of University College, London; Obstetric Physician to University College Hospital and the Great Northern Central Hospital; Teacher of Practical Midwifery, University College Hospital Medical School; Examiner in Obstetric Medicine to the Royal Colleges of Physicians and Surgeons. Illustrated with 503 engravings. New York: The Macmillan Company, 1910.

THE present edition of this well-known work represents a thorough revision of the last edition, which has also been largely rewritten. The authors have brought this work strictly up to date in revising the matter dealing with the development of the ovary and of the early ovum, the physiology of the fetus and of the puerperal state, the mechanism of labor, the lower uterine segment, the pathology of eclampsia, hydatidiform mole, accidental complications of pregnancy, narcosis in labor, vaginal and extraperitoneal cesarean section, and pubiotomy, and a new chapter has been added on injuries and diseases of the fetus. The authors have admirably presented a clear exposition of modern obstetrics, both as a science and as an art. The work is enriched by numerous illustrations of a high order of artistic merit, and remarkable for their clearness and simplicity. The typography is excellent.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-third Annual Meeting, Held at Syracuse, N. Y., September 20, 21, and 22, 1910.

THE PRESIDENT, DR. AARON B. MILLER, SYRACUSE, IN THE CHAIR.

Present Status of the Colon Tube.—Dr. H. WELLINGTON YATES of Detroit, in connection with his paper showed skiagraphs first of all to prove that fluids injected into the rectum were carried to the cecum. Second, that no device was necessary for this end except a small male catheter. Third, that within ten minutes this fluid could be skiagraphed in the cecum. Some of these pictures were taken with the patient in a dorsal position, some in the ventral and some in Fowler's position. The mixture was always injected by a small rectal tube or large male catheter inserted five inches. If done slowly, no trouble was had in injecting one quart even in the smallest subjects. His observations and conclusions were: 1. Seldom if ever were soft rubber tubes admitted into the normal colon. 2. When an endeavor was made to force the tube upwards even by the gentlest manipulations, it was found to coil itself up in the rectum and there did positive harm because of pressure, irritation and the consequent inability to retain the enema. 3. In perhaps half the instances it was impossible to tell when the tube was coiling up on itself even when they suspected it. 4. Colon tubes as such were of no value because they did not reach the colon and they were mischievous in that proportion as they endeavored to force them high up. 5. Water or fluid injected four or five inches into the rectum was carried upward into the colon and might be found at the cecum in ten minutes. 6. There was good reason to believe that a reversed peristalsis was set up when fluids were injected into the rectum. 7. The introduction of a tube more than five inches for colonic irrigation or therapeutic enemata was useless and likely to defeat the object desired.

Dr. LEWIS S. MCMURTRY of Louisville stated that he presumed that the experience of every member was like his own; that they satisfied themselves several years ago that they were practising a deception upon themselves by the use of what was called high enemata. It had been discovered that what they formerly called high enemata were not high enemata; that if they introduced a soft rectal tube into the bowel and kept on passing and passing the tube until it reached to the sigmoid it then began to coil upon itself and it did not pass into the bowel, so that years ago he abandoned all efforts at what were known as high enemata, recognizing that they were a deception. It seemed this had an important bearing upon some important features of treatment of the colon especially ulcerative conditions. For instance, if they opened the cecum they could irrigate the colon from below or above but if they had no opening in the caput coli they would find that it was almost impossible with the patient in any position, even inverted or in Hanes' position, to get water up into the transverse and ascending colon, but if they had an opening there and they threw water in, the gas would pass out of the opening in the cecum and gave them a means of medicating the entire mucous surface of the colon, but without such an opening it was impossible to do it.

Dr. J. GARLAND SHERRILL of Louisville said it had been demonstrated by Dr. Hanes that fluids passed with difficulty into the colon and cecum because of the amount of gas that was found in this portion of the bowel, and if they had an opening in the cecum or appendix the gas would come out and fluid would go in. Dr. Hanes used coal oil in the treatment of amebic dysentery with gratifying results.

Dr. LOUIS FRANK of Louisville wished to speak of the therapeutic value of injections of fluids for medication in bowel lesions situated high up by the use of the inverted posture.

Dr. FRANCIS REDER of St. Louis, Missouri, said that Dr. Soper and he had done considerable work in the field of rectal inflation and the injection of water into the lower bowel endeavoring to get it as high up as possible and they found that if they took an ordinary colon tube and introduced it into the bowel it was impossible to get above the promontory of the sacrum. The ordinary soft tubes coiled on themselves and the fluids injected did not reach beyond what was called the shelf of the rectum.

Dr. Yates, in closing, stated that he had proved conclusively that water did not pass the colon with the patient in the horizontal position. The purpose of his paper was to show the possibility of not only medicating the rectum, but the sigmoid and colon with fluids.

Diagnosis of Chronic Surgical Lesions in the Upper Abdomen.—Dr. CHARLES N. SMITH of Toledo, Ohio, in this paper stated that the diagnosis of these lesions was made with accuracy by the anamnesis alone. The differentiation of cholelithiasis from ulcer demanded the recognition of the initial symptoms, which were frequently overlooked. The accepted symptomatology of cholelithiasis and ulcer was largely that of their terminal events. The most striking feature of ulcer was periodicity of painful attacks alternating with intervals of relief. As complications occurred the attacks were more severe, becoming nearly continuous. In cholelithiasis the stomach distress, compared with the pain of ulcer, was of much less intensity, occurred sooner after the taking of food, than was the pain of a full stomach and did not progressively increase and reach its height in from two to five hours after meals. Cancer of the stomach was generally a sequence of ulcer, symptoms of the latter gradually merging into those of the former. Vomiting might or might not be a dependable symptom in cancer. Anemia was a most important symptom. Chronic pancreatitis being largely a terminal event in cholelithiasis, the diagnosis of the former was facilitated by recognizing the initial symptoms of the latter. Valuable pancreatic symptoms were found in the feces. Chemical and microscopical examinations were necessary. Cammidge's reaction was of questionable value. In movable kidney during Dietl's crises, the swollen and tender kidney, especially when jaundice was present, might be mistaken for an inflamed and distended gall-bladder. Differentiation was to be made from appendicitis, rupture of the gall-bladder and renal colic. The appendix might mimic successfully many of these lesions.

Dr. ROBERT T. MORRIS of New York said one could not always make a diagnosis of the presence of gall stones, and one should not fall into the trap of speaking of cholelithiasis. One should not make that diagnosis. It was a dangerous thing. One should speak of cholecystitis, as the gallstones were merely incidental to cholecystitis.

Dr. JOSEPH PRICE of Philadelphia stated that if the internists made diagnoses in these cases early and referred them to surgeons for operation promptly, many more lives would be saved than is now the case.

Dr. ROLAND E. SKEEL of Cleveland, Ohio, said if one wished to secure as complete and certain a history as was necessary to make a diagnosis in the cases under discussion, unusually intelligent patients must be met with, but he did not see any possibility of the average patient giving such an accurate history of his case as would lead the surgeon to make a diagnosis from that alone.

Problems in Uterine Cancer.—Dr. WALTER B. CHASE of Brooklyn, New York, first discussed the frequency, suf-

fering, and mortality attending uterine cancer which were a sufficient argument why professional sentiment should be thoroughly awakened to the necessities of the situation. In the present state of knowledge, early extirpation of the uterus offered the best chance of cure. Where there was considerable involvement of the vaginal structures, the first indication was high amputation of the cervix and removal of the vaginal involvement. If the uterine stump did not heal hysterectomy should usually be undertaken, providing there was normal mobility of the uterine body. Vaginal hysterectomy subsequent to cervical amputation was difficult if not impracticable. Fixation of the uterus if not dependent upon other coexisting causes contraindicated hysterectomy. Under such conditions accurate differentiation should be made. If the parametria were involved radical measures were contraindicated. When subsequent to the removal of the cervic and the vaginal growth hysterectomy was expedient, the abdominal route should be chosen because vaginal hysterectomy was neither easy nor practicable and because there should be as little interference as possible with the remaining cicatrix. The value of hysterectomy for cancer of the body as a secondary operation, though not recognized by the average practitioner, had a value which could not be gainsaid in a certain class of cases. The writer objected to the palliative treatment of uterine cancer most in vogue which consisted of the application of potent escharotics, both on account of the inability to limit the area of their destructive influences and the violent pain attending their application. The thermocautery was the palliative measure *par excellence*. The electric cautery left nothing to be desired, and if one was under the necessity of using a Paquelin, which was practically as satisfactory, it was hazardous to attempt the operation with a single apparatus. A variety of straight and curved platinum knives and hone-shaped instruments were needful. For securing the best results tact was needful in protecting the vaginal walls from excessive heat and skill in removing all diseased structures compatible with the anatomical relations of the healthy and diseased structure. His results from the use of the thermocautery had been very satisfactory. The *modus operandi* of the thermocautery treatment seemed to be, *first*, its power to destroy or inhibit specific germs beyond the area of actual destruction of tissue; *second*, it closed the lymphatics, thereby limiting absorption; *third*, it promoted healing, diminishing hemorrhage and purulent discharges; *fourth*, when the destruction of malignant growth extended to normal structure, it facilitated the advent of healthy cicatrization; *fifth*, by following the use of the cautery, by daily gentle irrigation with one of the cresol compounds, of not more than one dram to a quart, always avoiding peroxide of hydrogen, and dressing with oxide of zinc gauze, the suffering was greatly lessened and sometimes almost wanting until the inevitable end; *sixth*, well-authenticated cures had followed this treatment in which no expectation of cure was suggested. Dr. Chase then spoke of the necessity of disseminating such information among women as would vouchsafe to them such an appreciation of the necessity of the situation regarding cancer as to lead them to seek assistance early. He also urged that public interest be awakened among philanthropic men and women, as had been done for those suffering from tuberculosis, so that facilities might be provided for the care of the numerous cases of uterine cancer in those without financial resources. He introduced a series of resolutions to that end and hoped that the society would consider these questions in a practical way and he invoked the mature judgment, cooperation, and influence of the members in the formation of a plan and the promulgation of measures by which the condition of women with cancer would be ameliorated.

Statistics of Cancer in the Female.—Dr. K. I. Sanes of Pittsburg read a paper based on some statistical data collected from the latest eight annual reports of the Bureau of Census and the latest reports of 219 hospitals. The figures showed that the proportion of deaths from cancer to the total number of deaths from all cases were in females 1 to 17.7; in males 1 to 33.4; the proportion of deaths from cancer in the past twenty-five years to the total number of deaths in the past thirty-five years were, in females, 1 to 9.8; in males, 1 to 18.5. Taking the relative frequency of cancer in both sexes it was found that according to the mortality statistics of the United States Bureau of Census 62 per cent. of those that died of cancer were females and 38 per cent. males; according to the hospital statistics 66.5 per cent. were females and 33.5 per cent males. They saw that cancer was an exceedingly common disease in the female and it was met with about twice as frequently in females as in males. Whether based on mortality figures or population figures there was clearly shown an increase in cancer from 1900 to 1908. In the eight years there was an increase in cancer mortality from 1 to 22.8 deaths to 1 in 16.6 deaths, or from 63 per 100,000 population to 74.3. The question was frequently raised whether the gradual increase in mortality was not due to changes in the methods of reporting deaths and to the greater accuracy in the diagnosis of cancer, especially in view of the slight variation for the five years between 1903 and 1907. Hospital statistics, if carefully and properly compiled, could be utilized to great advantage by the profession in many ways. The modern hospital organization and facilities, the gradual increase of the number of hospitals all over the country, the more general use of the hospitals by the sick, the greater readiness by the profession and patients to adopt surgical measures for surgical diseases—all this made the hospital the most valuable source of statistical medical information. But to get accurate information, not only must each hospital have a careful, conscientious statistician, but the visiting members of the hospital staff must see that their diagnoses were carefully reported in the hospital records.

Dr. William H. Humiston of Cleveland, Ohio, said he had had but five cases of what was generally spoken of as inoperable cancer of the uterus, and in these he resorted to the Wertheim operation, making a very wide dissection, and of this number four were still living.

Dr. Ralph Waldo of New York stated there had been a decided advance in operative work for the treatment of cancer of the uterus. He believed to-day that most any one who was competent to pass judgment would advise a radical operation on any woman forty-five or fifty years of age who had a persistent hemorrhage from the uterus unless there was a polypus or something of that kind which he could thoroughly demonstrate was the cause of hemorrhage. They would occasionally take out a uterus at that age which was not the seat of tumor, but they would take out many more uteri that were the seat of incipient carcinoma. Generally he preferred the vaginal route in operating on these cases.

Dr. Maurice I. Rosenthal of Fort Wayne, Ind., said the early symptoms of cancer of the uterus were hemorrhage and discharge, and when they got a case of cancer of the uterus in its early history it was a pure incident. The only saving clause they had was the fact that some carcinomata were less malignant than others, or some were more malignant than others, and when they were dealing with carcinoma of the fundus of the uterus they were ordinarily dealing with a carcinoma that was less malignant, and a destructive operation through the vagina in such a case was uncalled for. When they were dealing with carcinoma of the portio vaginalis they were dealing with that form of cancer which was not so malignant. In such cases ordinary hysterectomy done with cautery would give as good results as any other method. When they were dealing with carcinoma of the portio uteri

which began in the endometrium higher up, they were dealing with a serious malignant growth that practically no operation would do any good. He had done the Wertheim operation, and reported fifty-seven cases some years ago with good results.

Dr. J. H. Carstens of Detroit agreed with Dr. Rosenthal and Dr. Waldo that it was largely a question of early diagnosis. When a woman had cancer which was so far advanced that the lymphatics and other structures were involved it was better to let her alone and trust to the *vis medicatrix naturæ*.

Dr. Thomas B. Noble of Indianapolis looked upon cancer of the cervix or of the uterus as an analogue to carcinoma of the breast. It should be so considered and diagnosticated and decidedly so with regard to treatment.

Dr. Joseph Price of Philadelphia looked upon the vaginal operation as one of the simplest in surgery, but in operating for the removal of carcinoma of the uterus where the structures were involved and wide and deep dissection was necessary it was better to operate through the abdomen.

Dr. Francis Reder of St. Louis, Mo., stated the whole question resolved itself into early diagnosis, skilled operative measures, and education of patients.

Dr. Edward J. Ill of Newark, N. J., stated in operating for cancer of the uterus no surgeon could open up an extensive area of cellular tissue without spreading the cancer cells. The safest operation, where there was any extent of cervical carcinoma, was to start from above, separate all adhesions, separate all attachments to the uterus and to its surroundings, and then go from below and lift the mass right out and cut it off with a cautery, as had been suggested by Werder.

Treatment of Obstruction of Bowels Due to Malignant Neoplasm.—Dr. Maurice I. Rosenthal of Fort Wayne, Ind., in this paper reported advanced cases of carcinoma of the bowel treated by simple anastomosis without resection. He spoke of the advantages of this method in such cases. He described a method by which anastomosis was accomplished before the bowel was actually opened, making the bowel suture aseptic. He described the operation in detail, illustrating each step. No new or complicated instruments were required. He spoke of the advantages of the Murphy button in situations that were not sufficiently accessible for this operation. He reported cases of radical resection of the malignant bowel and spoke of the futility of resection unless it could be done radically. He gave the general results from operations for cancer of the bowel as shown by a review of 328 cases from the literature.

His conclusions were as follows: 1. Obstruction of the bowel due to carcinoma was not hopeless as to cure by radical operation. Incomplete excision of all cancerous tissue must necessarily result in recurrence of the growth. 2. Anastomosis without resection of the malignant growth should be the operation of election in obstruction due to cancer, where the radical operation, that was complete excision, was impossible. 3. Anastomosis without resection low in the pelvis, where the bowel was accessible with difficulty, could be successfully accomplished by the assistance of the Murphy button. 4. Anastomosis without resection probably bore the same relation to cancer of the bowel as did gastroenterostomy to cancer of the pylorus. 5. The clamp and suture method of bowel anastomosis as described was practical, rapid, and trustworthy, and applicable in a large variety of bowel cases requiring resection or anastomosis.

Diagnosis of Tubal Abortion and Rupture.—Dr. Charles E. Congdon of Buffalo, N. Y., stated the general indication for operative interference as promptly as possible could not be gainsaid. Schauta, for example, after a careful study of the literature, collected 123 operative cases, with a mortality of 5.7 per cent., and 121 cases treated palliatively, with a mortality of 86.89 per cent., although in another series of more carefully selected cases he found the mortality by palliative treatment to be only 65 per cent. To recapitulate the diagnostic features he would say that (1) there was sudden pain, nearly always, the exceptional cases being those with sudden collapse, as in two cases which he reported in July, 1909. (2) Uterine hemorrhage occurred within forty-eight hours after the initial pain. This symptom and sign was common to all cases of rupture or abortive tubal pregnancy. (3) Add collapse and the diagnosis was complete. If collapse was lacking or slightly marked it was on account of gradual internal hemorrhage when on examination the cul-de-sac would show a progressive bulging.

Results at Lebanon Hospital of Deferred Operations for Extrauterine Pregnancy.—Dr. Ralph Waldo of New York stated they had had many patients brought into the hospital in a very desperate condition, and out of the eighty-one cases that he reported there had been but three deaths. It was thought that two or three patients would die in the ambulance. They were freely stimulated and reached the hospital moribund. At no time after reaching the hospital would they have stood an anesthetic or the slightest operation. Autopsies proved the diagnosis of ruptured extrauterine pregnancy to be correct. The third patient who died was one of those unfortunate cases that were occasionally met with by all surgeons, where the patient was making an absolutely normal convalescence, when she suddenly died from pulmonary embolism. Seventy-eight other cases were operated on by the abdominal route, and recovered. After a severe hemorrhage another did not take place in less than from a week to ten days. In from two to seven days, depending upon the condition, the abdomen was opened from above. The clots and free blood were rapidly removed with the hand and dry gauze sponges, but the abdominal cavity was never irrigated. Formerly, where the patient had lost a large amount of blood, they put a quart or two of normal saline solution in the abdominal cavity, and left it there to be absorbed. More recently this saline had been given in rare instances in the cellular tissue by hypodermoclysis, or more frequently in the rectum. In one instance only in the above cases was the abdomen drained; in all others it was closed. The entire operation required from eight to twenty minutes. He preferred the abdominal route because the operation could be performed much quicker, and when the mass was high up and the vagina small, much better. It might be well for him to state that he performed many operations on the tubes and ovaries through the vagina. He was not prejudiced in favor of the abdominal route.

Dr. L. F. Smead of Toledo, Ohio, stated a woman, twenty-five years of age, was brought to him with a diagnosis of ectopic pregnancy. This was her second pregnancy. Her first pregnancy was cared for by a physician who brought the case to him so that they knew the exact condition. At the same time there were no abnormal symptoms. The history of the case was that for two or three days there was slight pain in the right side, and during the night preceding the day upon which he saw her there was a slight flow. There was no tenderness in the abdomen particularly, and on vaginal examination he found a slight mass over the right cornu of the uterus. The things he considered were these: First, he considered it possibly tubal with a slight rupture into the broad ligament; *second,* interstitial pregnancy in the cornu, and *third,* he considered the possibility of a simple development of the placenta in the right horn of the uterus. The uterus was fully as large as it should be at about three months. As the examination was quite satisfactory with her abdominal muscles quite relaxed, he

decided later that probably a threatened abortion was taking place with the placenta in the right cornu of the uterus, and he decided to treat the case in that light, as he was not anxious to open the abdomen in a normal pregnancy or overlook interstitial pregnancy in the cornu of the uterus. Two months have elapsed since he saw her. The symptoms had disappeared and apparently a normal pregnancy was progressing.

Dr. H. W. Longyear of Detroit stated this matter of deferred operation in extrauterine pregnancy in the presence of shock had been threshed out in this association several times, and if he remembers rightly the consensus of opinion had been decidedly in favor of immediate operation. It was his opinion that operation should be done in these cases even in the presence of extreme shock. He knew of no other class of cases in which they waited in the presence of hemorrhage for shock to cease. They operated primarily for the stoppage of hemorrhage, and to wait for shock to cease in some cases would be fatal.

Dr. J. H. Carstens of Detroit stated that Dr. Longyear had struck the keynote. If they had a hemorrhage from a leg that had been cut off they did not wait for shock to subside, but they stopped the hemorrhage. He believed in operating on these cases promptly.

Dr. William H. Humiston of Cleveland, Ohio, had had an unusual record in cases of ruptured tubal pregnancy, that is, he had yet to have his first fatal case, and he operated on them as soon as he could get them ready for operation and get his instruments there and assistants. He did not care what condition the patient was in, whether in shock or not.

Dr. Henry S. Lott of Winston, N. C., wanted to emphasize the character of the pain. Several times he had made a diagnosis of ectopic pregnancy in the early weeks by sitting by the side of the bed of the patient and watching her for several hours, and the pain was always recurrent, rhythmic, and explosive, whereas if the appendix was the seat of trouble the pain was continuous without intermissions, and very often without remissions.

Dr. J. Garland Sherrill of Louisville agreed with Drs. Carstens and Humiston. If they had a ruptured vessel internally they considered it one of the most dangerous forms of hemorrhage they had to deal with. If they had a case of gunshot wound of the abdomen they would not wait to open that abdomen. The same course therefore should be pursued in cases of ruptured extrauterine pregnancy.

Dr. E. Gustav Zinke of Cincinnati stated there were exceptional cases. Extrauterine pregnancy was not always the same in every case. Some of these patients recovered without operation. They found these symptoms when they operated for other conditions. Tubal pregnancy terminated in three different ways, namely, tubal abortion, and the ovum became absorbed and an operation was not necessary by any means in every case. Then they had a rupture between the layers of the broad ligaments, and they had a ruptured tube into the peritoneal cavity. In the case of rupture between the layers of the broad ligaments they had a well defined tumor form. In the case of rupture into the peritoneal cavity they had sudden shock and all the signs of internal hemorrhage, and that was a case in which prompt action was indicated, and it was for the operator to decide whether an operation should be performed at once or whether he had time to wait. In those cases in which the tube ruptured into the peritoneal cavity with severe hemorrhage with all the symptoms of shock, in which the picture was complete, they did not see the patients in the hospital, but usually at their homes or in places where opening of the abdomen was prohibited. It would mean death to operate at once, because the surgeon was not prepared and the patient was not prepared. Experience had taught us that by putting these patients in the recumbent position and keeping them there with an ice bag over the abdomen and lowering the head and preparing to operate, that often within half an hour or an hour improvement in the patient's condition took place. The pulse came up, began to get stronger, and with the apearance of a stronger pulse, on digital examination they felt the formation of a tumor through the vagina. In cases where that tumor did not appear the vaginal vault became more or less flattened. There was no resistance. They felt nothing apparently. In these cases hemorrhage goes on, and they were the ones that must be operated on at once, for if operation was not done they would die. But in the other instances where a tumor formed they could afford to wait longer, and encapsulation would take place and the patient could be operated on with absolute safety within a few days or even weeks.

Dr. Lewis S. McMurtry of Louisville stated the diagnosis was easy in these cases. He had known women who had had one attack of tubal pregnancy, and were operated on, to make the diagnosis themselves in the second instance and call the doctor and tell him the condition that existed. He had one instance of that kind in mind then, and there was no trouble with the diagnosis and the treatment. When a woman was bleeding to death inside there was only one indication and that was to operate as soon as possible.

Dr. Charles L. Bonifield of Cincinnati wanted to emphasize the point that in these cases by the time the operator got to the patient usually the hemorrhage had taken place and the surgeon did not operate to stop hemorrhage, but to relieve shock because in the majority of cases the hemorrhage had already stopped. The patients bled profusely and did so quickly until blood pressure was relieved, and then the bleeding was slow until it stopped entirely.

Dr. Walter B. Chase of Brooklyn stated every member of this association believed he was grounded in the principles of surgery, but they had different methods of reaching the same end. They could not make a universal rule which would apply to every case of tubal pregnancy. The man who attempted to do it would go wrong more than half of the time. Every case must be treated according to the findings, and according to whether the physician was prepared to treat it at the time.

Dr. Joseph Price of Philadelphia felt that cases of ruptured ectopic pregnancy and all perforative forms of disease belonged to the calamities, and they should be prepared to operate promptly. The surgeon should be the cleanest and most prepared man living.

Dr. Congdon, in closing the discussion on his part, stated it was not always his policy to cross swords with his friends, but when they made the assertion that the diagnosis of ectopic pregnancy was always easy and that any one can make it without any preparation he certainly must take exception to that statement. The members of this association meant that they could make a diagnosis but not the average general practitioner.

Dr. Waldo, in closing, said a mistake that was made much more frequently than any other was that the patient was suffering from incomplete abortion.

Tumors of the Bladder.—Dr. John F. Erdmann and Dr. Joseph F. McCarthy of New York read a joint paper on this subject. The authors reported ten cases in detail and drew the following conclusions: that tumors of the bladder were translatable by the symptomatic hematuria, etc., which did not always permit clinically of a striking difference between them inasmuch as a small papilloma might give rise to a fatal hematuria, as well as a malignant one. However, one might arrive in certain cases at a precise diagnosis based upon the clinical evolution, the physical signs, and the examination of the fragments ex-

pelled. That the benign tumors might recur under two forms, first under the malignant form, a long period of time intervening before the recurrence; and it was a question whether the tumor beginning as a benign one had not become transformed into a malignant one. The actual state of knowledge of the subject did not at this time permit of this conclusion. A recurrence might take place after a long period of time as a benign one as in two cases recorded by Dr. Erdmann with histological findings. Guyon stated that "the cases which I believe have permitted of this hypothesis of a transformation are very exceptional. I have already had an occasion to cite in studying the progress of neoplastic affections of the bladder many examples of vesical tumors of long duration even up to twenty-seven years, which did not undergo malignant transformation. Consequently one should be very reserved in discussing the question of transformation of vesical growths." As to the mortality the authors quoted Dr. Francis S. Watson as follows: "The sum and substance of the result of operative treatment up to the present time may be stated thus: If the operative deaths and rapid recurrences are combined under the head of operative failures, such failures are seen to have occurred in 28.6 per cent. of cases in benign tumors, exclusive of myoma and in 46 per cent. of cases of carcinoma." According to the same author, out of six hundred and fifty-three cases of all tumors operated upon two hundred and forty-three were benign and four hundred and ten malignant. The benign tumors recurred rapidly in 20.5 per cent., the carcinomatous in 26.8 per cent., and the sarcomatous in all except two of fifty-two cases.

Dr. James E. Sadlier of Poughkeepsie, N. Y., wished to report the case of a woman, 60 years of age. Cystoscopic examination of the bladder showed a tumor on the right side, somewhat posterior, but well above the right ureteral orifice, the tumor at its base being about the size of a silver dollar. It was protruding into the bladder and the surface had a sloughing appearance. The base was thick and indurated and with a forceps through a Kelly cystoscope he was enabled to remove a fragment or two, which the pathologist pronounced to be epithelioma undergoing carcinomatous change. In this case he tried the perineal operation as suggested by Dr. Charles Mayo and found it to be a comparatively easy operation.

Dr. Joseph F. McCarthy of New York stated that those who had anything to do with these growths knew they recurred with great frequency, and if there was any method of treating the smaller ones that did not involve a radical operative procedure, they should welcome it. Within the last few months Dr. Keyes and Dr. Beer of New York had treated these growths by fulguration or high frequency. He treated one case in which there were four growths by this method with gratifying results.

Dr. John W. Poucher of Poughkeepsie said he had no argument to offer in regard to operative procedure for the removal of papilloma of the bladder, but he wanted to suggest something he had tried very successfully in the treatment of urethral caruncle. He had treated urethral caruncle for the last five years with a strong solution of argyrol and had not failed in a single case.

Dr. John W. Keefe of Providence, R. I., wanted to say a word about the use of the cystoscope. He was not wedded to the use of the water cystoscope because he had failed to find tumors in the bladder on account of severe hemorrhage that occurred at the time the water cystoscope was used. With the air cystoscope these growths could be readily seen. With reference to the transperitoneal operation it should be performed more often than the operation just above the pubes in the prevesical space, especially if the patient was fat, as they had a deep wound in which to operate. By placing the patient in the Trendelenburg position they could readily have access to the bladder.

Dr. Louis Frank of Louisville said that tuberculosis of the bladder was exceedingly rare as a primary lesion. It was always secondary to tuberculosis in other portions of the genitourinary tract. So true was this that they could practically always exclude it as a cause of bladder disease. His experience with tumors of the bladder was confined to one or two cases. In these he was able to bring the growth up by the vulsellum forceps so as to remove them extravescially. The growth was excised, the base cauterized, and the bladder wall brought back and immediate closure effected, and catheter kept in. One case, which was operated on three years ago, had not had a recurrence. In the other case the tumor of the bladder was complicated or associated with hypernephroma.

Adenocarcinoma of the Kidney.—Dr. J. Garland Sherrill of Louisville reported a case of a somewhat rare tumor of that organ, with histological findings. He mentioned briefly the various forms of renal tumor, especially hypernephromata. In the earlier writings much confusion existed with reference to nomenclature and the descriptions of renal tumors, but recent writings had brought a clearer understanding. Traumatism was mentioned as a factor in the etiology. Although a history of trauma in a considerable percentage of cases was given there was no conclusive evidence that it was important in causing the growth. As important symptoms he mentioned hematuria, failing health, pain in the back and loins. The diagnosis of renal tumor was not always easy and differentiation before operation as to the character of the growth was usually not possible. While the mortality following nephrectomy for malignant disease was higher than for some other lesions demanding such treatment, it should be very low when done early with their present technique. From one-half to one per cent. of carcinomata primarily affected the kidney. According to Kelynack two or three per cent. was a fair proportion of malignant growth of the kidney to malignant disease of other parts. A number of cases were collected from the literature by the writer, two of which were congenital, and in one case a number of calculi were present. Males seemed to suffer almost twice as often as females. Heredity seemed to play no important part in the development of these growths. They had no positive knowledge of the causative factors in the production of these tumors, but it was probable that a large proportion were of congenital origin, due to cell rests. A number of cases of injury of the kidney subsequently followed by carcinoma had been reported. Although the position of the kidney rendered it especially free from traumatism, in a number of cases traumatism was reported as having caused the first hemorrhage which called attention to the affection. Calculus had been claimed by some to be an important causative factor in the production of renal carcinoma, but the question yet remained *sub judice*. The author then discussed the diagnosis, the symptoms, and prognosis of these tumors. The present mortality of nephrectomy for malignant disease was from 18 to 20 per cent., which should be reduced, in his opinion, by early diagnosis and prompt intervention. The only hope of recovery offered the patient suffering from malignant disease of the kidney lay in early and complete nephrectomy. Partial nephrectomy had been practised at least five times for malignant tumor, according to Morris, but in every case the surgeon thought he was dealing with benign tumors and the results were not encouraging. In advanced cases palliation was always to be offered to the patient. The author reported a case in which through an oblique left lumbar incision nephrectomy was performed, resulting in recovery. Upon incision through the kidney and growth after its removal the organ was found to be 6 inches in length by 2½ by 2 inches. At the lower pole an irregularly rounded nodular mass was observed. A number of branching vessels were seen on the surface of the tumor. On palpation

it was not so resistant as the other portion of the kidney, and a few whitish spots were seen. On section the kidney appeared slightly congested with a tumor 3 inches in diameter at the lower pole, apparently encapsulated with infiltration into the parenchyma and also into the fat about the pelvis. Inside the capsule was a grayish-white mass of material a little firmer than thick cheese. The remaining portion of the kidney showed some congestion, but the tissue appeared to be almost normal except where the growth was infiltrated through what might be termed the capsule.

Dr. John F. Erdmann of New York had operated on five cases of tumor of the kidney, four being hypernephromata, and one a large sarcoma.

Dr. Lewis S. McMurtry of Louisville stated with reference to the pathology it was very doubtful if the analogy between the relation of stones in the gall-bladder, stones in the kidney, and the development of malignant disease could be established here. There seemed to be in the kidney with the presence and irritation of stone, on account of the different character of the tissue, and the different function of the tissue a greater disposition to suppuration than to malignant disease, whereas in the gall-bladder they could not regard it as thoroughly established that the irritation of gall-stones was a distinct factor in the development of malignant changes.

The Breast of the Expectant Mother; Its Care Before and During the Period of Lactation.—Dr. Francis Reder of St. Louis said that to prepare a nipple properly the expectant mother was instructed to use soap and water freely. After drying the breast, gentle friction with a rough towel or flesh brush was made for about five minutes. Following this rubbing the nipple was massaged by rolling and kneading it between the fingers, gentle traction being made during these manipulations. The free use of olive oil during the process of massage, which was to be done twice daily, was advised. It was surprising how an almost hopeless appearing nipple would in a comparatively short time assume the characteristics of a normal one. The application of alcohol and astringent lotions was to be condemned. A nipple cared for with these agents would become hard and inelastic, presenting deep corrugations, which would impede the healing of any excoriation or fissure, should such a lesion occur. The pain accompanying such a lesion brought many hours of suffering to the mother. A nipple prepared by the method of a systematic massage would usually withstand the strain of the nursing period without mishap. Its care after the child had commenced to suckle resolved itself into one of simple cleanliness. Thorough ablutions after each nursing to free it from any accumulated secretions and the liberal dusting with boric acid, which was washed off when the child was put to the breast, were all that was necessary. This régime must be diligently adhered to. The care of the breast was as important as that of the nipple. Its anatomical structure gave evidence of how readily this organ was amenable to culture, if only instituted properly and at the right time. The breast of a healthy girl that did not show development conforming to the incentive given by puberty should after an elapse of three years be subjected to the stimulating influences of a systematic massage. This massage was to be continued until a normal equipoise had been attained. By developing the breast at this stage of womanhood many of the obstacles pertaining to a normal motherhood might be overcome. The massage in reality was an exercise most simple in character. By placing a breast in the palm of each hand and locking the fingers across the chest, the young woman was asked to walk about in a well-aired room, and with a full inspiration force the hands apart. This exercise was to be repeated for at least 15 minutes daily. It was most conveniently carried out upon rising and before retiring, and should be continued until satisfactory results showed themselves. The normal breast of the expectant mother should receive some attention as soon as the physiological changes manifest themselves. The breast during the pregnant state did not require the judicious management that the breast demanded after lactation had established itself; it was of the greatest import, especially if the breast gave evidence of great fullness and tension with tenderness, that the lactiferous ducts be maintained in as patulous and healthful a state as was possible. In short, the secretions in the tubes should not be allowed to become stagnant. It has been demonstrated that the staphylococcus albus and also the staphylococcus aureus found entrance into the milk ducts from the skin. That this so-called milk fever was the result of these microorganisms having gained entrance into the lactiferous ducts and having been stimulated into great activity by finding a proper medium in the milk for their propagation had been to him the only explanation.

Dr. Theresa Bannan of Syracuse had been looking for milk fever, which was referred to by the essayist, for 20 years in practice and had not found it. The question of the care of the nipple of the expectant mother was of far-reaching and tremendous importance. It solved 50 per cent. of the problems of pure milk. It meant not only the health of the mother, but the life not only of the first child, when most of the difficulties arose, but all of her subsequent children.

Dr. William G. Dice of Toledo stated it was the general practitioner who was at fault to a great extent. He thought most patients were willing to take proper care of their breasts if given proper instruction. He did not recall seeing in his practice more than two cases of abscess of the breast in 10 years.

Dr. A. J. Rongy of New York thought the term milk fever had been eliminated from obstetrical work. In a record of 6,000 cases in both hospital and maternity work they practically did not have what was known as mastitis. They never had cases of suppurative mastitis. It seemed to him the trouble with these engorged breasts, or with so-called milk fever, was in doing too much for the patient rather than doing too little.

Dr. J. H. Carstens of Detroit was opposed to the application of alcohol or tannic acid and other astringents to the breast. The nipple of the mother should be soft and pliable.

The President's Address: Gynecology.—The President, Dr. Aaron B. Miller of Syracuse, after speaking of the recent advances that had been made in obstetrics, gynecology and abdominal surgery, said the scope of work of the members had gradually increased since the knowledge of bacteriology had illumined the way to a more accurate diagnosis and given them a known pathology. He quoted the prophetic statement made by J. Marion Sims in 1882 to the effect that it would become possible to open the abdomen in gunshot and stab wounds, to repair and thereby lessen the mortality attending these injuries. In the master mind of Sims the seeds of advancement had taken lodgment. His observations and associations abroad had given him an oversight into the possibilities of the future, the possibility of surgery becoming a science, founded on findings that were indisputable. With the advent of bacteriology came a new school of surgeons whose knowledge was founded on facts, not theories, and like the mariner who consulted his compass, had known laws to direct them. The field of gynecology, the pelvis, with the abdomen appended, was their hunting ground, and like an army marching to victory, the field was soon taken. Now all the organs of these cavities, abdomen and pelvis, had felt the results of advancement and had yielded of their pathology abundantly; and not pathology alone, as the organs of this casket had even been maimed and sacrificed in their healthy state for reasons that at times would have shocked Hippocrates, and should arouse them, as it was the pur-

pose of this association according to its constitution, to advance the knowledge of obstetrics, gynecology, and abdominal surgery to its highest scientific attainment, to enlighten the general practitioner in all matters pertaining to these different departments, by eliminating the erroneous teachings, and accentuating the essential; to stamp with approval all real merit and extinguish sham. The knowledge of the real etiology of disease robbed surgery of its terrors and opened the pelvic and abdominal fields for investigation through a perfect technique, with but little fear of serious consequences attending thorough exploration, thereby revealing the living pathology and rendering the arrest or elimination of disease possible. In the obstetrical art marked results had been obtained through a knowledge of infection. From a heavy death rate following confinement from these causes, the technique carried out in hospital practice had almost eliminated the mortality. In the field of gynecology, the disease that stood as a lone sentinel against the advancement of science, yielding not its etiology, was cancer. Having existed since the early history of medicine, it had withstood all investigation. While all forms of maladies had crumbled in ruins about it, it had continued its ravages until many thousands of people in the United States were dying annually of this disease. The recognition of cancer of the breast and treatment in its inception by early operation had resulted in a greater percentage of cures and materially lessened the mortality. It was the consensus of opinion that cancer of the stomach had its origin on the site of an ulcer. Prophylactic treatment prevented the cancer by curing the ulcer. Prophylaxis must be introduced in the prevention of cancer of the uterus by early repair of lacerations. Traumatism was the accepted factor in inducing cancer of the breast, and following upon or secondary to lesions in the viscera, as stomach, gall-bladder, pancreas, lip, etc., reasoning by analogy that with its increased frequency at the neck of the uterus in parous cases, the presence of lacerations would be an exciting cause for its presence here encouraged through the degenerations that took place, and as a preventive measure, repair of the injuries would in many cases arrest it. Reference was made to the havoc caused by gonorrhea and syphilis. He said that gynecologists had been slow to impress upon the public and to enlighten women especially as to the great dangers that threatened them through ignorance of these diseases that were liable to be brought to them through unsuspected avenues. This subject had been enshrouded in mystery that boys and girls had grown to mature manhood and womanhood ignorant of the laws that should govern their lives, for fear that the knowledge of sexual diseases might lead to contamination. Gynecology in its inception should be begun as with the tender plant. Proper environment should be placed about the growing child to aid in development and to protect when dangers threatened, thereby promoting stronger healthier bodies.

Puerperal Wound Intoxication and Wound Infection; A Historical and Critical Review of Childbed Fever.—Dr. Henry Schwarz of St. Louis said isolated cases of puerperal fever had occurred at all times among civilized nations, but the dreadful epidemics of this disease appeared with the advent of the lying-in hospitals and they became more dreadful when frequent autopsies were made in the search of the cause of the disease. Oliver Wendell Holmes was the first to point out the contagiousness of puerperal fever and the means for preventing it. His epoch-making essay, "The Contagiousness of Puerperal Fever" appeared in 1843. Semmelweis in 1847 was second to insist on the same points and to demonstrate the correctness of his views by reducing the mortality from childbed fever in his Vienna clinic. The appeals of Holmes and Semmelweis remained unheeded until the advent of Listerism and the establishment of bacteriology. Hungary, the native country of Semmelweis, had honored his memory by having his ashes removed from Vienna and depositing them in an honor-grave at Budapest; a memorial tablet pointed out the house in which he was born; a grand Semmelweis monument had been erected on one of the finest squares in Budapest. The medical profession of the United States had almost forgotten that Holmes had equal if not greater claim to be remembered as the discoverer of the nature of puerperal fever. Most text-books did not mention him while they did justice to Semmelweis; the one pleasing exception was the text-book of Barton Cooke Hirst. Bacteriological classification had caused many teachers to fail to present to their students a clear subdivision of clinical pictures, and while the writer insisted on the necessity of ascertaining the nature of the infecting germ by smears and cultures, he likewise insisted on the advantage of sharply separating wound intoxication or sapremia from wound infection, and of subdividing wound infection into the milder and more or less localized forms which usually got well, namely, puerperal ulcers, puerperal endometritis, puerperal parametritis, puerperal perimetritis, and puerperal phlebothrombosis, and into the general infections which were inclined to be fatal, namely, pyemia, general peritonitis and general sepsis. At present the medical profession was fully acquainted with the nature of puerperal infection and with the means which would absolutely prevent it. In well-managed institutions infection had been driven out, but nevertheless thousands of young mothers died yearly in the United States whose lives could be saved. Who was to blame? The cause lay partly in the inadequate obstetrical training which the medical schools until recently provided; this cause was now rapidly disappearing. The principal cause lay in the fact that throughout the United States a large part, in the large cities the greater part, of the obstetrical work was done by midwives and that with few exceptions no laws existed regulating the practice of midwives. The writer pleaded for the enactment of such laws and for putting the schools for midwives under control of State boards. The exceptions were Missouri, Louisiana, Ohio, Wyoming Utah, and the Philippine Islands; their laws provided for examination and registration, but not for control of the schools. Maine and Mississippi especially declared that their medical practice acts did not apply to midwives; the law of Mississippi said: "Females engaged in the practice of midwifery were not prohibited from such practice, but were entitled to engage therein without a license."

Serum Therapy and Bacterial Vaccines in the Treatment of Puerperal Septicemia.—Dr. Henry Schwarz of St. Louis stated that since Marmoreck's antistreptococcic serum was placed upon the market in 1895 the writer had used the various antistreptococcic sera in those cases of severe acute puerperal sepsis which, according to his judgment, were hopeless under other forms of treatment. The first case in 1896 was one of severe pyemia and recovered; no bacteriological diagnosis had been made. In all other cases cultures made from the blood proved the presence of streptococci; every one of these cases died. Streptococci were found in the blood oftener than was formerly supposed, even in the more or less localized infections, but in these the serum was not employed. When bacterial vaccines were recommended in the treatment of acute infections the writer considered such use not only hopeless and illogical, but he feared that it would injure the reputation of vaccines in their legitimate field. In acute streptococci infections billions of streptococci were found in the blood; they died by millions and their bodies were dissolved, liberating thereby the endotoxin which during life was retained in the capsule, but which now swamped the system. The formation of anti-bodies under such conditions was very feeble or at a standstill; to inject millions more of dead germs, with their endotoxins, showed

as much sense as the injection of morphine into a patient dying with morphine poison. To prove his contentions the writer caused to be undertaken a series of experiments on rabbits, which proved the following points: 1, Vaccination after inoculation had no influence on the infection; all animals died in three days, the same as the control animal. 2. Vaccination simultaneous with inoculation had no influence on the infection; all animals died in three days, the same as the control animal. 3. Prophylactic vaccination produced immunity, but it must extend over a considerable period and vaccination must be stopped ten days before inoculation. Intraperitoneal and intravenous vaccination prolonged the duration of the infection so that animals so vaccinated died two days later than the control animal. Subcutaneous vaccination alone was effective and animals vaccinated every four days from July 24 to August 28 and inoculated September 7 remained well, while the control animal died in three days. Excessive vaccination (50,000,000 to 200,000,000 in average weight animals) produced no ill effect beyond a temporary refusal of food. The experiments were being continued.

Acute Pancreatitis.—Dr. John W. Poucher of Poughkeepsie, N. Y., reported two cases. In his first case the fever only began after the action of the ferment had destroyed the function of the intestines and probably other organs in the abdomen. In the other case prompt and efficient drainage prevented any serious action upon the tissues of the organs. In this case there never was more than a slight rise in temperature. His experience in these two cases seemed to point to two conclusions, namely, early and free incision down to the pancreas and adequate drainage.

Acute Hemorrhagic Pancreatitis.—Dr. John W. Keefe of Providence, R. I., reported eight cases of this disease, and said that these cases were of interest from several standpoints. Two cases recovered of the eight cases reported. Two patients were operated on twice. One was operated upon for acute hemorrhagic pancreatitis and 1½ years later was again operated upon and four gall-stones removed from the gall-bladder. Dr. Giles of New Hampshire reported a similar case. He operated for acute hemorrhagic pancreatitis and his patient was operated upon about one year later by Dr. Irish and a number of gall-stones were removed. Another case in this series was operated upon for acute hemorrhagic pancreatitis and some months later a pancreatic cyst was removed. The events were reversed in one of the cases. Thirty-two gall-stones were removed, but a stone was left in the common duct. The patient some months later died from acute hemorrhagic pancreatitis. They should keep in mind the close relationship between infection of the bile passages and disease of the pancreas. While they should strive to make more accurate diagnosis in lesions of the abdomen, in obscure conditions they should not delay, but should operate early, as most of the conditions that simulated pancreatic disease require surgical interference.

Perforated Gastric Ulcer.—Dr. Thomas B. Noble of Indianapolis, Ind., reported two cases of peritonitis due to perforated peptic ulcers. These cases were the first and only of their kind he had seen. The pathology and symptomatology were very analogous to perforation of any hollow viscus of the abdomen. The diagnosis must depend upon the recognition of a demonstrable peritoneal insult as evidenced by sudden, severe pain about the umbilicus or epigastrium, with local tenderness, followed by vomiting and the general symptoms of shock. Careful inquiry revealed a period of gastric disorder antecedent to the acute attack. Symptoms of acute peritonitis, more or less general in character, rapidly ensued, and it might be that they would overshadow all others at the time of observation as happened in his first case.

Public and Private Hospitals.—Dr. Joseph Price of Philadelphia pointed out the importance of these hospitals in the education of young physicians and nurses and the clinical instruction of practitioners.

Torsion of the Great Omentum.—Dr. William J. Gillette of Toledo, Ohio, said the diagnosis prior to operation was difficult and uncertain. He pointed out the diagnostic signs that were available; also spoke of the frequency of this condition and its mortality, 13 per cent., should warrant its more careful study. The case he reported was unusual and made it probable that death from gastric and colonic hemorrhage as a consequence might ensue.

Cesarean Section.—Dr. J. H. Carstens of Detroit reported a case in which the pregnant uterus was within an umbilical hernia. Mrs. M., aged 40 mother of three children, widow for 10 years, married again one year ago, grew very fleshy. She became pregnant and toward the end it was found that the uterus was in the hernial sac and the abdomen pendulous, hanging down to the knee. On vaginal examination the uterus could not be felt. It was pulled up. Cesarean section was resorted to and followed by a smooth recovery.

High Operation in Cesarean Section.—Dr. William H. Humiston, Cleveland, Ohio, emphasized the substitution of the Cesarean section for the high forceps operation which was attended with a mortality to the mother of 10 per cent. and to the child of nearly 21 per cent. The technique employed in the modern Cesarean operation had been so perfected and the indications for the operation so widened that it was now frequently resorted to in order to give both mother and child greater chances for life. The rapidity with which this operation could be safely performed by an experienced abdominal surgeon was an important factor for the safety of the mother and the life of the child. Modern aseptic technique and favorable surroundings were essential and would insure practically a nil mortality, provided the mother had not already been infected by repeated examinations and efforts to deliver. In all cases in and near a city or town, where hospital accommodations were modern, the patient should be transported to such an institution for operation and convalescence. Dr. Humiston detailed a case in which he resorted to the high operation with success.

Cesarean Section by the Small Median Incision Above the Umbilicus.—Dr. Asa B. Davis of New York stated that of the 78 Cesarean sections performed by him the first three were done in tenements; the uterus was delivered. Since August 12, 1903, he had done the operation 75 times and in no instance had the uterus been removed from the abdomen. Beginning with case four a much smaller incision was used, half above and half below and to the left of the umbilicus. In the seven cases following this one he gradually made the incision smaller and carried it higher up, until November 20, 1904, he, so far as he knew, first independently conceived and practised the small, high median incision entirely above the umbilicus, in a woman, the twelfth of his series, it being the second Cesarean section done on this woman, the same as case four. More than two years after this date an allusion to the high incision was brought to his attention in Blundell's "Midwifery," published in 1842. There was no reason why this operation should be singled out from all others as one which must be performed in great haste. It should be done with the deliberation called for in any other abdominal operation. There was great danger in doing otherwise. Several times the writer had found the intestine in front of the uterus. Once he had seen it injured. The incision should be long enough to allow easy delivery of the child, but the abdominal wall at this point in the full-term woman was thin and stretched easily. The small high incision did not allow easy exposure or escape of the abdominal contents. Not infrequently all

that he saw was the uterus and a small portion of omentum. This wound was away from the site of greatest strain upon the abdominal wall, at a point reinforced by the recti muscles as they approached each other toward their upper attachments. It was small. He had never seen hernia following it.

Secondary Repair of Complete Perineal Lacerations; Its Technique and Results.—Dr. Edward J. Ill of Newark, N. J., said there were still many failures resulting from the operation for complete laceration of the perineum. His first operation after the method to be detailed was done February 1, 1891. A doubtful case of improvement had the power of perfect retention within a few months. Altogether 56 cases were reported, all of which showed remarkable and uniform success. Twenty-six cases were complicated by other operations. In his operations he followed the principle laid down by Saenger, in the Tait operation in 1887. The operation was essentially a flap-splitting operation and could be divided into six distinct steps: 1. The incision. 2. The flap splitting. 3. The suture of the rectum. 4. The suture of the perineum. 5. The suture of the vagina. 6. Twisting of perineal sutures. The operation he described was a modification of the Saenger-Tait operation. Incisions were of H-shape, beginning at a point just outside of the orifice of Bartholin's glands, extending downward and backward just outside of the retracted sphincter. The cross-bar of the H was carried exactly across at the mucous membrane of the rectum and vagina. Two flaps were formed, an anterior and posterior. The posterior one denuded the ends of the torn sphincter. The suture of the rectum was done with the finest catgut in the denuded tissue of the posterior flap. He preferred silver wire for the perineum. Three sutures took care of the sphincter. The fifth step consisted of suturing the anterior flap of the vagina. He urged great exactness in the coaptation of the wound when twisting down the sutures of silver wire. These sutures were cut on the ninth day. The after-treatment consisted of moving the bowels in 48 hours, preceding the act of defecation by a sweet oil injection. It was best to have the first movement with the patient on her left side the nurse supporting the newly made perineum. Urination was usually normal, and the patient was allowed to sit on the commode rather than to be catheterized. The patient should be well aware of her retention powers at the time the sutures were removed.

Intussusception in Infants.—Dr. Herman E. Hayd of Buffalo, N. Y., said that the treatment of this condition was surgical, and the mortality increased tremendously the longer the operation was delayed. Injections, irrigations, and insufflations were too uncertain to be practical and scientific, but in recent cases they were often of value in assisting subsequent reduction after the abdomen was opened. The operation should be done quickly, and no time should be lost in fruitless manipulations of the bowel. It was better generally to eviscerate at once and reduce the mass outside than try to effect its reduction within the belly cavity. Dr. Hayd detailed a successful case on which he had operated.

Conservatism in Operations on the Uterine Appendages.—Dr. Lewis C. Morris of Birmingham, Alabama, drew the following conclusions: 1. No woman under 40 years of age should have all of both ovaries removed, except in the presence of tuberculosis or cancer. 2. Resection or amputation of diseased parts and plastic work on the tubes would occasionally be followed by conception. 3. Even in the presence of infection and more or less involvement of both tubes and ovaries plastic work, followed by pelvic drainage and the Fowler position, might be followed by regeneration. 4. Radical or sacrificial surgery and conservative surgery had about the same *mortality*, but a vastly different morbidity. 5. A very occasional secondary operation might become necessary which might have been avoided by doing radical work.

Intravenous Injection of Magnesia Sulphate in Bacteriemia.—Dr. Raleigh R. Huggins of Pittsburg stated that in the study of drugs causing hyperleucocytosis, it was determined to find out, if possible, whether magnesium sulphate might act in this manner when administered intravenously. After a careful study in both rabbits and the human, it was decided that it did not produce a regular increase in the leucocytes when thus administered. During this study a number of intravenous injections of magnesia sulphate were administered to human beings. It was determined that magnesia sulphate could be given intravenously without any apparent harm to the patient. Experiments showed that a 1 per cent. solution of magnesia sulphate in a normal saline would not produce hemolysis of the human blood. It would not precipitate the globulins, as claimed by Teubusher, when given in this dilution, nor had the writer seen any effect upon the specific gravity of the urine. It was decided that 30 grains of magnesia sulphate in 8 ounces of normal saline could be safely administered intravenously to the average individual. It must be given slowly into the vein at a temperature of 105° to 108°. The time occupied in allowing this quantity to run into the vein was 20 minutes. If allowed to flow into the vein rapidly, respiration became embarrassed, and the patient complained of heat all over the body. It had been given in this manner fifty times either by the writer or his assistants, and the results in many instances had been extremely gratifying. It had been given at intervals of twenty-four hours for several days. It was during this study that it was determined to try its use in a patient suffering from puerperal infection. A number of cases, which were beginning a typical course, similar to others who died in spite of all treatment, had been treated by intravenous injections of magnesia sulphate with apparent benefit. Its use had been limited almost entirely to the treatment of puerperal infection, and the number of cases treated were too few to draw any conclusions.

Fibromyomata of the Uterus Complicating Pregnancy, Labor and the Puerperium.—Dr. Ralph Waldo Lobenstein of New York read a paper which was based upon a study of one hundred cases occurring at the New York Lying-in Hospital. The chief deductions from this series of cases were: 1, A myomatous condition of the uterus predisposed to sterility. Parvin stated that while the average sterility was one in eight, it was one in three in women with myomata. Charpentier's figures correspond closely to these. 2. The tendency to abortion was increased. In the bad cases, both spontaneous and artificial abortion might prove difficult to handle by the natural channel, and was most dangerous to the life of the individual. In the severe cases, where it was difficult to gain access to the cavity of the uterus proper, and in the presence of real hemorrhage, laparotomy was the operation of choice. 3. The great majority of the cases that did not abort early proceeded through pregnancy, labor, and the puerperium with few or no symptoms; therefore, operative interference was but rarely indicated during pregnancy and was, as a rule, meddlesome midwifery. He made this statement cautiously, for he knew well that in the minds of many it would be open to criticism. The operation of myomectomy during pregnancy was just now very popular, but he for one believed it was rarely indicated. The results of myomectomy were none too good. Occasionally it might be wise to do a myomectomy, and occasionally necessary to do a hysterectomy, but as a rule conservatism should be the watchword. 4. Nature accomplished wonders at the time of labor, overcoming any apparent dystocia, in a large percentage of cases. When delivering, avoid all possible trauma to the tumor. 5. With

the development of the symptoms of gangrene in a myoma in the puerperium, operate early to save the life of the patient.

Two Right-Sided Femoral Hernias in the Same Patient.—Dr. N. Stone Scott of Cleveland reported an interesting case, and the points of special interest, as illustrated by him, were the rarity of external femoral hernia; the importance of making a correct and accurate diagnosis; the possibility of the coexistence of an external and internal femoral hernia on the same side of the patient; the ease of overlooking the external when it was associated with the internal or more common form; the operative technic of the external femoral hernia was not essentially different from that of internal femoral hernia. Lastly, where both varieties were operated on the same side, great care was necessary to prevent interference with the functions of the blood vessels.

Puerperal Eclampsia.—Dr. E. Gustav Zinke of Cincinnati read a paper on this subject in which he drew the following conclusions: 1. All cases of puerperal eclampsia were not alike; much depended upon the extent the kidneys and liver were involved. The so-called malignant form, as the term implied, was fatal from the beginning. The so-called benign variety ended in recovery sometimes in spite of the treatment adopted. The variety of mean gravity was without doubt favorably influenced in its course by careful and judicious treatment. 2. The prognosis for both mother and child was much worse when the convulsions supervened during pregnancy, the maternal mortality ranging between 35 to 50 per cent.; the fetal mortality between 65 and 75 per cent. The prognosis of intrapartum convulsions was more favorable, maternal as well as fetal, and amounted to about 25 per cent. The maternal mortality of postpartum convulsions was, as a rule, about 7 per cent. In his own experience, having had but two cases, it was 50 per cent. 3. The most important treatment of puerperal convulsions was prophylaxis before the appearance of symptoms as well as before the eclamptic attacks when prodromal signs existed. The patient must be protected from injury during the convulsions and the duration and frequency of the paroxysms should be controlled and abbreviated medicinally rather than surgically. Veratrum viride in sufficiently large doses was the remedy par excellence to reduce the blood pressure and the pulse frequently. Hoth baths and hot packs, judiciously employed, and free but not excessive catharsis, strict milk diet, and the recumbent position were of almost equal importance. 4. Chloral in large doses per rectum, if the patient was very restless during the interval of the attacks, was a splendid remedy. Chloroform inhalations, especially of long duration, could be regarded as a source of great danger. The same might be said of frequent and large doses of morphia, the both of these drugs having their ardent advocates. 5. The antitoxin treatment (the thyroid, parathyroid extract, and nephrine) might play an important part in the future in the treatment of eclampsia. 6. Saline and sugar water instillations could do no harm and might do a great deal of good. 7. If, of late years, the maternal mortality of puerperal eclampsia had been reduced at all, it was the direct result of careful prophylaxis and intelligent medical care. Surgery had contributed nothing to it. The dictum, "assist in labor, but do not induce it," or "treat the convulsion and let the pregnancy take care of itself," was better than the dictum, "empty the uterus as soon as possible in every case of puerperal convulsions, no matter what the period of gestation." 8. Decapsulation of the kidneys, manual, balloon, and mental dilatation, especially the old time accouchement forcé, were, in the opinion of the author, hardly justifiable and should have no place in the treatment of puerperal eclampsia. 9. If, however, the symptoms were very threatening and the medical care above described failed to bring about promptly an amelioration in the patient's condition, an early delivery might be desirable. If the patient be near term, but not in labor, the conservative Cesarean section should be selected. If the patient was just within the period of viability, vaginal hysterotomy was the proper procedure. If the fetus was not viable before the end of the sixth month of gestation, deep cervical incisions would easily relieve the uterus quickly of its contents. 10. No one had a right to perform any of these three operations unless experienced and familiar with the technic of each, and in every instance the patient should have the benefit of strict asepsis. Without these requirements it was best to rely entirely upon the medical care above outlined.

Pelvic Reflexes.—Dr. Robert T. Morris of New York spoke of afferent and efferent reflexes, and said in a certain proportion of patients with pelvic reflexes there was the neurotic habit. These patients were neurasthenics. If a surgeon took out one ovary for pelvic pain, the patient was just as badly off as before the operation. If the other ovary was removed, she was just as badly off as before. The surgeon must deal with neurotic patients with a great deal of intelligence. They represented a class calling for surgery, but the surgeon should beware of patients with pelvic pains, ovarian and tubal troubles, and neuralgic pains, particularly those of the neurotic or neurasthenic type. We had a group of disturbances proceeding from a scar of the cervix. How were we going to determine whether we were to operate in a case of reflex trouble with a torn cervix? Very many patients had torn cervices. Did the cervix require operation for its repair? Did we do the right thing if we operated because we found tears and scars? No. We were not to operate in such cases unless there were definite reasons for so doing. If one should press on a scar of the cervix with his fingernail, or with the sharp point of a retractor, and bring out instantly that reflex, then the case was one requiring operation for reflex disturbance; but if one should press on a scar and the patient did not know it, or if one should press on another scar and the patient did not know it, we should not operate on that case, no matter how much the cervix was torn, for the relief of reflex disturbance. One might operate for a repair of a torn cervix on general mechanical principles, but not for the object of relieving the efferent reflex.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Herman E. Hayd, Buffalo, N. Y.; *First Vice-President,* Dr. Henry Schwarz, St. Louis, Mo.; *Second Vice-President,* Dr. Lewis C. Morris, Birmingham, Ala.; *Secretary,* Dr. William Warren Potter, Buffalo, N. Y.; *Treasurer,* Dr. X. O. Werder, Pittsburg, Pa.

Louisville, Ky., was selected as the place for holding the next annual meeting; time, fourth Tuesday in September, 1911.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Pennsylvania Medical Examining Board.

June, 1910.

ANATOMY.

1. Give the origin and insertion of the rectus abdominalis muscle, and describe in detail its relationship to other structures.

2. Give the relations of the peritoneum with the bladder in the distended and collapsed condition.

3. Give the lower border of the pleura on each side in the anterior axillary line.

4. Describe the seventh or facial nerve, and give its distributions.

5. Give relation of bony prominences of the elbow joint in the flexed position.

6. Through what structures of the eye does light pass to reach essential visual structure?

7. Describe the stomach, and give its relationship with other organs.
8. What are the relations of the right kidney, and why is it lower than the left?
9. Describe the formation of the deep and superficial palmar arch with the anatomical landmarks of each.
10. Give the location and structure of the inguinal canal and name its normal contents.

PHYSIOLOGY.

1. Explain in detail the mechanism of intestinal peristalsis.
2. Name three physiological conditions which help to protect the body against disease or injury; citing instances of protective immunity.
3. Enumerate four conditions to be observed in "taking" the pulse, and describe the significance of each.
4. Describe the functions of the liver.
5. Discuss calorifaction with special reference to the maintenance of normal temperature.

PATHOLOGY.

1. Discuss carcinoma uteri with special reference to the age at which it commonly occurs.
2. Name the casts that may be found in the urine and state what is the usual significance of the presence of each form.
3. Describe the pathologic tissue changes in the varieties of pulmonary emphysema.
4. Discuss "fatty" degeneration of the heart.
5. Discuss uremia and state conditions to which it is due.

PRACTICE AND THERAPEUTICS.

1. What are the symptoms which are most characteristic of typhoid fever in its early stages?
2. How would you treat a case of angina pectoris during and between attacks?
3. What are the characteristics of acute articular rheumatism, and how would you treat it?
4. What are the causes of asthma, and how would you treat an attack of bronchial asthma?
5. Give the method of using the cold bath treatment in typhoid fever.
6. How would you treat a case of uremic coma occurring in chronic Bright's disease?
7. Describe the way in which you would vaccinate a patient.
8. How would you manage a case of epilepsy during and between attacks?
9. Describe the prophylactic and curative management of malaria.
10. Name the most characteristic lesions present in the different stages (primary, secondary, and tertiary) of syphilis.

SURGERY.

1. Describe how you would locate on the skull the point to trephine in hemorrhage from the middle meningeal artery.
2. Describe the symptoms produced by loose bodies in the knee joint, with the treatment of same.
3. What conditions are capable of causing stricture of the rectum; describe a surgical operation for the relief of any one form.
4. Give symptoms upon which to base a diagnosis of ulcer of the stomach, and describe a surgical operation for the relief of same.
5. Describe the methods of examination to determine whether a tumor of the breast be malignant or benign.
6. Diagnosticate stone in the urinary bladder and describe suprapubic cystotomy.
7. Describe a backward dislocation of the shoulder joint, and give treatment for same.
8. Describe four of the more usual varieties of fracture at or about the elbow joint with the appropriate dressings for each form.
9. What are the contraindications and dangers of ether and chloroform anesthesia?
10. Name the common causes of ununited fracture and discuss the measures resorted to for its cure.

MATERIA MEDICA.

1. Compare the effects of the two principal alkaloids of opium, and name the drugs that are antagonistic to opium.
2. State to what class of remedies stramonium belongs, and describe two other official drugs belonging to this class or group.
3. What is tartar emetic, and into what official preparations does it enter?
4. Name the salts of manganese, giving their dose and describing their action.
5. Write a prescription for the production of mydriasis, with directions to the patient, and explain its use in refraction.

CHEMISTRY.

1. How are blood and pus chemically detected in the urine?
2. Describe method of use when testing for glucose with Trommer's, Fehling's, or Haines' solution.
3. What is indoxyl-potassium sulphate? Describe a chemical test for its detection.
4. Describe chemical tests for three forms of urinary calculi.
5. Describe a test for the diastasic activity of digestants ("extracts of malt").

DIAGNOSIS.

1. Name five causes of coma and give the characteristic symptoms produced by each.
2. Diagnosticate pernicious anemia and differentiate conditions simulating it.
3. Differentiate impetigo, lichen, and pemphigus.
4. What are the most important defects of vision, and how would you differentiate them by the use of test-cards, lenses, and mydriatics?
5. Differentiate stone, tubercle, and carcinoma of the kidney, giving chemical and microscopical tests of the urine in each.

HYGIENE.

1. Give hygienic and dietetic measures for preventing constipation.
2. What are the dangers from the use of drugs for the preservation of foods?
3. Outline the dietetic and hygienic instructions suitable for a person who has contracted syphilis.
4. What are the possible results of the use of tobacco by growing children in regard to circulation, vision, and air passages?
5. State briefly some practical method for securing good ventilation in houses not properly ventilated at the time of building.

OBSTETRICS.

1. Describe the delivery of the after-coming head.
2. Diagnosticate a shoulder presentation and describe the method of delivery.
3. How would you diagnosticate ectopic pregnancy?
4. During labor what conditions should govern the employment of an anesthetic?
5. What means should be employed to prevent laceration of the perineum?
6. How would you diagnose and treat albuminuria of pregnancy?
7. Discuss the use of "the forceps."
8. Name causes and describe the management and treatment of uterine inertia.
9. Enumerate causes of dystocia and describe the management of any one form.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA MEDICAL EXAMINING BOARD.

June, 1910.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 426; or Gray's "Anatomy" (1908), page 444.
2. See Cunningham's "Anatomy" (1909), page 1153; or Gray's "Anatomy" (1908), page 1444.
3. On *right* side to lower border of ninth rib; on *left* side to lower border of tenth rib.
4. The *seventh or facial nerve* has its superficial origin in the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. It passes "forward and outward to enter the internal auditory meatus; it lies upon a groove on the auditory nerve, with portio intermedia of Wrisberg between, and at the bottom of the meatus it enters the aqueductus Fallopii, along which it runs first outward between cochlea and vestibule as far as hiatus Fallopii; then backward in internal wall of tympanum, just above fenestra ovalis, at the turn presenting a swelling, the geniculate ganglion; and finally it passes downward, to emerge from the bone at the stylomastoid foramen; it then passes outward and forward in the parotid, dividing behind the ramus of the jaw into temporofacial and cervico-facial branches, which further subdivide and intercommunicate, forming the pes anserinus."—(*Aids to Anatomy.*)

It *supplies* the muscles of expression in the face, the muscles of the external ear, the Platysma, Buccinator, Stylohyoid, and the posterior belly of the Digastric.

5. When the elbow is flexed, the tip of the olecranon process lies below a line joining the two condyles of the lower end of the humerus.

6. Cornea, aqueous humor, lens, vitreous body and on to retina.

7. See Cunningham's "Anatomy" (1909), page 1050; or Gray's "Anatomy" (1908), page 1277.

8. See Cunningham's "Anatomy" (1909), page 1130; or Gray's "Anatomy" (1908), page 1422.

9. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches. The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm. The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries. The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch. Wounds in this region are dangerous on account of the difficulty in checking the hemorrhage, and also on account of the important structures of the palm that may be damaged. In incision in the palm the line of these arteries should be avoided as far as possible.

10. The *inguinal canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries are: In front:* the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind:* the conjoined tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above:* the fibers of the internal oblique and transversalis. *Below:* Poupart's ligament and the transversalis fascia.

Contents: the spermatic cord in the male, and the round ligament in the female.

PHYSIOLOGY.

1. See Gray's "Anatomy" (1908), page 1330.

2. (1) The epithelial covering, and in some places the presence of cilia to remove the germs; (2) the acidity of the gastric juice, which will kill bacteria; and (3) the phagocytic action of the leucocytes.

3. The points to be observed in taking the pulse are: (1) Its *frequency:* this gives the rate of the heart beats. (2) Its *compressibility:* this denotes the force with which the heart is beating. (3) Its *tension:* this denotes the peripheral resistance, and also the state of the arterial walls. (4) Its *regularity or rhythm:* this denotes the regularity (or otherwise) of the heart's action in force or rhythm.

4. The functions of the liver are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

5. The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

PATHOLOGY.

1. Carcinoma of the body of the uterus is far less frequent than that of the cervix, it also occurs later in life, the majority of cases being seen between fifty and sixty years of age. Carcinoma of the cervix is very frequent, it attacks almost exclusively women who have borne children, it is most frequently observed between thirty and sixty years of age, generally near or at the menopause, but cases have been seen as early as twenty.

2. "*Casts* in the urine occur in nephritis, and different varieties are found in the different forms of that disease. *Hyalin* casts occur in all forms of nephritis, in congestion of the kidneys, in jaundice, and even in health. *Waxy* casts occur especially in chronic parenchymatous nephritis. *Epithelial* casts occur especially in acute parenchymatous nephritis. *Granular* casts are especially common in chronic nephritis, but they may occur in acute nephritis. *Fatty* casts occur chiefly in chronic parenchymatous nephritis. *Blood* casts occur in acute and chronic hemorrhagic nephritis. *Pus* and *bacterial* casts are occasionally met with in suppurative nephritis."—(From Stevens' *Practice of Medicine.*)

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 773; or Da Costa's "Surgery" (1908), page 705.

2. See Rose and Carless' "Surgery" (1908), page 675; or Da Costa's "Surgery" (1908), page 579.

3. *Stricture of the rectum* may be congenital; or may be due to malignant tumors, cicatrization of wounds or ulcers (syphilitic or tuberculous), cellulitis, bands of adhesion, gonorrhea, and traumatism. For *treatment*, see Rose and Carless' "Surgery" (1908), page 1140; or Da Costa's "Surgery" (1908), page 1021.

4. See French's "Practice of Medicine" (1907), pages 748 and 750; *and* Rose and Carless' "Surgery" (1908), page 991; or Da Costa's "Surgery" (1908), pages 827, and 829.

5. See Rose and Carless' "Surgery" (1908), page 954.

6. See Rose and Carless' "Surgery" (1908), pages 1212 and 1217; or Da Costa's "Surgery" (1908), pages 1132 and 1141.

7. See Rose and Carless' "Surgery" (1908), page 622; or Da Costa's "Surgery" (1908), pages 588 and 590.

8. See Rose and Carless' "Surgery" (1908), pages 506, etc.; or Da Costa's "Surgery" (1908), page 493, etc.

9. The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "Ether should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma: and if anemia is present and an examinatiin of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although either is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

Dangers of Anesthesia: Syncope, or cardiac failure; respiratory embarrassment with obstruction (muscular spasm, tongue falling back, spasm of the glottis, entry of blood or other matter into the larynx) overdose of the anesthetic, shock.

10. See Rose and Carless' "Surgery" (1908), page 484; or Da Costa's "Surgery" (1908), page 460.

MATERIA MEDICA.

1. Codeine is very like morphine in its action, but it (codeine) is less powerful as a hypnotic and analgesic; it is also less liable to cause nausea, and constipation; it is less depressing to the cerebral functions, and less poisonous to the medulla; it is generally weaker than morphine, and has but little effect on the respiration.

Antagonists to Opium: Strychnine, atropine, caffeine; and to some extent also, quinine, digitalis and tartar emetic.

2. *Stromonium* belongs to the same class as belladonna and hyoscyamus; these are classified by Wilcox as cerebral stimulants, by Potter as motor excitants, by Butler as mydriatic narcotics, by Stevens as cerebral excitants.

Belladonna leaves are "Usually of a dull brownish-green color, the leaves much wrinkled and matted together, frequently with the flowering top intermixed; leaves from 6 to 20 Cm. long, 4 to 12 Cm. broad, broadly ovate, apex acute, margin entire, narrowed into the petiole, upper surface brownish-green, lower surface grayish-green, epidermis more or less papillose, particularly on the under surface; odor distinctly narcotic, especially on moistening; taste somewhat bitter and acrid." *Belladonna root* is "in cylindrical or somewhat tapering, longitudinally wrinkled pieces, 1 to 2.5 Cm. thick, the bark somewhat incurved at the edges of roots which have been split before drying; externally pale brownish-gray, dusty or mealy, outer layers of the periderm rather soft, frequently abraded, and thus showing lighter patches; fracture nearly smooth, mealy, and emitting a characteristic puff of dust; internally whitish, the older roots showing medullary rays near the bark; nearly inodorous, taste sweetish, afterward bitterish and strongly acrid." *Hyoscyamus* has "leaves ovate or ovate-oblong, the lower with a short petiole, the uppper sessile, 5 to 25 Cm. long, 2 to 10 Cm. broad, acute, coarsely and angularly toothed or lobed, grayish-green, glandular-hairy, particularly on the lower surface; flowers nearly sessile, with an urn-shaped, unequally 5-toothed calyx and a campanulate, purple-veined corolla, which in the fresh state is yellowish; fruit capsular, 2-celled, and enclosed in the calyx; odor heavy, narcotic; taste somewhat bitter and nauseous."—(*U. S. P.*)

3. Tartar emetic is antimony and potassium tartrate. It enters into the composition of compound syrup of squills, and of wine of antimony.

4. Precipitated manganese dioxide, dose gr. iv; manganese hypophosphite, dose gr. ij; manganese sulphate, dose gr. iv; potassium permanganate, dose (in pill), gr. j. "*The salts of manganese* in small doses improve the appetite and digestion, increase arterial tension, and stimulate the action of the heart. In larger doses they lower the heart's action, paralyze the muscular system, especially the muscular coat of the arteries, causing progressive wasting, paraplegia, and acute fatty degeneration of the liver. They are gastrointestinal irritants, have specific excitant action on the uterus, and the sulphate is a decided cholagogue."

Uses of Potassium Permanganate: "As an antiseptic and oxidizing agent it is used in diphtheria, scarlatina, septicemia, etc., and is given with benefit in dyspepsia, lithemia and obesity. Locally it is employed as a deodorizer in cancer, ozena otorrhea, foul breath, and fetid perspiration of the feet, in solution of 3j to the pint. It is considered a very efficient emmenagogue by many authorities, and is employed in amenorrhea and other derangements of the menstrual function. When used internally it must be instantly decomposed in the stomach, and cannot be absorbed in its own form. It has recently come into prominence as an antidote to morphine and strychnine in the stomach."—(Potter.)

5. R. Atropinæ sulphatis.....gr. j
Aquæ destillatæ .....3ij. M.
Signa: Poison. Put one drop in each eye every four hours.

It will paralyze the sphincter of the pupil, and stimulate the dilator. It is used to paralyze the accommodation, in order to estimate the refraction.

DIAGNOSIS.

1. The following table (from Eisendrath's *Surgical Diagnosis*) gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

2. See French's "Practice of Medicine" (1907), pages 510 and 512; or Osler's "Practice of Medicine" (1909), pages 726 and 729.

3. *Impetigo contagiosa* is an acute, contagious, inflammatory disease of the skin, characterized by discrete, flat, superficial vesicles or blebs, which rapidly become pustular and dry upon the skin as thin crusts. The eruption is most common upon the face and hands. *Lichen ruber* is an inflammatory disease of the skin characterized by the appearance of small, flat, angular, and shining or discrete, acuminated and scaly, reddish papules, running a chronic course and attended by more or less itching. The disease is of neurotic origin and infrequent. *Pemphigus* is an acute or chronic inflammatory disease of the skin, characterized by the formation of successive crops of variously sized, rounded or oval bullas, affecting seriously the general health and often terminating fatally. The blebs of pemphigus are tense, abruptly elevated, noninflammatory, and come out in crops.—(From Gould and Pyle's *Pocket Cyclopedia.*)

4. *The defects of vision* are: Hypermetropia, myopia, astigmatism, and presbyopia.

Test for hypermetropia: "When the vision is tested at a distance, it will be found perfect unless the patient has lost his accommodation, but he will see as well with a convex glass. The strongest convex lens through which the patient sees as well as without, measures the manifest hypermetropia. A cycloplegic such as homatropine hydrobromate

(2 per cent. solution) dropped into the eyes three times during an hour, or atropine sulphate (1 per cent.) three times a day for three days, will paralyze the accommodation, and the vision will then fall below the normal, because the patient can no longer use his accommodation and bring forward the focus upon the retina. The convex lens, which then gives him perfect vision, will be stronger than that for the manifest hypermetropia, and measures the exact refraction of the eye or total hypermetropia. The difference between the manifest and total hypermetropia is called the latent hypermetropia. As one grows older, the accommodation weakens, and the latent hypermetropia becomes less until about fifty or fifty-five, when the manifest equals the total, if it does not before."

Test for myopia: "The distant vision is found considerably reduced, while perfect at the near point. Concave spherical lenses bring the distant vision to normal if there are no complications. The weakest concave lens which gives perfect vision measures the myopia. Atropine is not so important as in hypermetropia, since there is a natural tendency to relax the accommodation. Low degrees of myopia, however, should be tested with a cycloplegic, because spasm of accommodation, or false myopia, is possible, and gives poor vision, improved by weak concave lenses."

Test for astigmatism: "The vision is affected according to the degree of the astigmatism, both for near and distance. Cylinders at the proper axis will give improvement in vision. Atropine should be used for the examination under the same conditions as in hypermetropia. A further subjective test is made with a card having lines which radiate in all directions from the common center, like spokes of a wheel. The astigmatic eye will not see all the lines with equal distinctness, and cylinders can be tried at all axes until the lines appear alike."

Test for presbyopia: "The near point of monocular vision is about two and one-half inches in the young child. This near point gradually recedes until between forty and forty-five it is no nearer than fifteen inches, which is the average reading distance. When the near point of accommodation recedes beyond this point and vision is not clear within this limit, the condition becomes unpleasant for reading, writing, and other near work, and is known as presbyopia."—(Alling's *Epitome on Diseases of the Eye.*)

5. See Rose and Carless' "Surgery" (1908), pages 1175, 1172 and 1183; or Da Costa's "Surgery" (1908), pages 1110 and 1115.

CHEMISTRY.

1. Test for *Blood:* To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

Test for *Pus:* Add an equal quantity of solution of potassium hydroxide to the urine; if pus is present a viscid gelatinous mass will be produced.

2. *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of traces of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c; and solution II of 130 gms. of Rochelle salt dissolved in 500 cc. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

3. Indoxyl-potassium sulphate is indican. *To examine for indicanuria:* "The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000, of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one or two minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess."

4. Three forms of urinary calculi: (1) Uric acid calculi; (2) ammonium urate calculi, and (3) triple phosphate calculi.

Chemical tests: Saw the calculus in two, take some of the sawdust and heat it on a platinum foil. If it is entirely volatile, take a fresh portion of the dust, moisten with nitric acid, evaporate to dryness at a low heat, add some ammonium hydroxide solution; a red color will be produced. Treat a portion of the dust with solution of potassium hydroxide, but without heating; if an ammoniacal odor is observed, the calculus is *ammonium urate;* if no such odor is observed, the calculus is *uric acid.* Take some of the sawdust and heat it on a platinum foil; if a residue remains, moisten a portion with nitric acid, evaporate to dryness at a low heat, add some ammonium hydroxide solution, no red color is produced; heat it before the blowpipe, on platinum foil; if it fuses, the calculus is *triple phosphate.*

5. The solid extract of malt should be dissolved in nine parts of water; this should be slightly turbid and give an abundant precipitate very shortly after being mixed with an equal volume of picric acid.

HYGIENE.

1. See French's "Practice of Medicine" (1907), page 806; or Osler's "Practice of Medicine" (1909), page 527.

2. The *dangers from the use of drugs for the preservation of foods,* are: (1) That the normal digestive functions will be impaired; (2) the food is less nutritious and more insipid; (3) that improper food will be so used, and because "drugged," will to some extent escape detection; (4) that there is no likelihood that any care will be exercised to add only the minimum quantity of preservative.

3. "Every person who contracts syphilis should be warned of the danger of communicating it to others. Sexual intercourse should always be prohibited while the disease remains active. This direction should never be omitted, as many patients are unaware that they are liable to communicate the disease after the initial manifestation has healed. The contagious nature of the lesions of the mouth and throat should also be pointed out, and the consequent risk of contagion by kissing, or by the use of drinking-vessels, towels, or other articles in common with other persons.

"Syphilis is essentially a debilitating disease, hence it is most important that the general health of the patient should be supported by nourishing diet, good air, warm clothing, extreme moderation as regards alcoholic liquors, cleanliness, cheerful society, and moderate exercise in the open air. In nearly all cases the patient should follow his usual employment, in order that his mind may be diverted from dwelling on the slow progress of his cure. The skin should be stimulated to act freely by the frequent use of soap and water, and an occasional Turkish bath if thought desirable. Flannel should be worn next the skin, and sudden chills avoided as much as possible. Smoking in moderation may be allowed, as long as the mouth and throat remain free; but when syphilitic lesions are present, it should always be discontinued. Regular action of the bowels is also important. Exercise, short of fatigue, should be taken daily, unles the weather is very bad."—(From Quain's *Dictionary of Medicine.*)

4. "The continued use of tobacco, by smoking or chewing it to excess, produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability, and occasionally angina pectoris. Used by the young, it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with nrocesses of digestion and assimilation. It has been credited with causing cancer of the lips and tongue, blunting the moral sense, mental aberration and even insanity."—(Potter's *Materia Medica,* etc.)

5. Proper ventilation may be secured by having double windows, or double panes of glass, with an opening at the bottom of the outer and at the top of the inner one, so that the fresh air may enter in an upward current.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 425; or Hirst's "Obstetrics" (1909), page 838.

2. See Williams' "Obstetrics" (1909), page 799; or Hirst's "Obstetrics" (1909), pages 426 and 433.

3. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the

size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua in part or whole Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-Book of Obstetrics.*)

4. See Williams' "Obstetrics" (1909), page 321; or Hirst's "Obstetrics" (1909), page 329.

5. See Williams' "Obstetrics" (1909), page 317; or Hirst's "Obstetrics" (1909), page 334.

6. See Williams' "Obstetrics" (1909), pages 176 and 520; or Hirst's "Obstetrics" (Edition of 1909), pages 253 and 249.

7. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior. (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both. *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must have been ruptured; (4) the diameters of the pelvis must be of sufficient size.

8. See Williams' "Obstetrics" (1909), page 659; or Hirst's "Obstetrics" (1909), page 439.

9. See Williams' "Obstetrics" (1909), page 658; or Hirst's "Obstetrics" (1909), page 439.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery.	Montgomery	Jan.
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 8
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	Los Angeles	Dec 6
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan. 3
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 13
Dist. of Col'ba	Geo. C. Ober, Washington	Washington	Jan. 10
Florida*	J. D. Fernandez, Jacksonville	Palatka	Nov. 9
Georgia	T. H. Goss, Athens	Atlanta	
Idaho*	W. F. Howard, Pocatello		April 4
Illinois	J. A. Egan, Springfield	Chicago	
Indiana	Crawfordsville	Indianapolis	Jan. 10
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	
Kentucky	J. N. McCormack, Bowling Green	Louisville	Dec. 15
Louisiana	E. L. McGehee, New Orleans	New Orleans	
Maine	F. W. Searle, Portland	Portland	Nov. 8
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 13
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Nov. 8
Michigan	B. D. Harrison, 205 Whitney Building, Detroit	Ann Arbor	June 13
Minnesota	W. S. Fullerton, St. Paul	St. Paul	April 4
Mississippi	S. H. McLean, Jackson	Jackson	
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	
Montana*	Wm C. Riddell, Helena	Helena	April 4
Nebraska	C. A. Carr, Lincoln	Lincoln	Nov. 9

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of October 15, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	492	153
Diphtheria	222	10
Measles	67	2
Scarlet Fever	88	1
Smallpox	—	—
Varicella	17	—
Typhoid Fever	149	20
Whooping Cough	19	5
Cerebrospinal Meningitis	3	5
Malarial Fever	—	—
Totals	1,057	196

A New Reaction in Typhoid Fever.—Silverstrini states that the subcutaneous injection of ¼ to ½ c.c. of a killed bouillon culture of typhoid bacilli causes in the typhoid patient a rise of temperature. In the typhoid convalescent there is a sharp febrile reaction, which is accompanied and followed by an increased agglutination. The reaction is specific.—*Clinica Medica Itáliana.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended October 14, 1910.

PERNICIOUS ANEMIA; ITS DEFINITION AND TREATMENT.*

By DR. E. GRAWITZ,
BERLIN, GERMANY.
PROFESSOR AT THE UNIVERSITY OF BERLIN; DIRECTOR OF INTERNAL DEPARTMENT OF THE KRANKENHAUS CHARLOTTENBURG-WESTEND.

PERNICIOUS anemia has been known for more than sixty years and the literature has been the subject of much discussion. The symptomatology is described by most of the authors in almost the same way. But notwithstanding there is up to the present time no agreement as to what we should designate as pernicious anemia.

Even a few years ago it was a generally accepted view to summarize under this term all those cases that exhibited during life the most severe symptoms of anemia, without the presence of a depleting organic disease or parasites, cases which even post mortem only showed certain secondary organic alterations as a result of an anemic condition of the blood, but no such changes as could account directly for the etiology of anemia.

Consequently, in the progress of etiological research certain types of anemia were eliminated, as, for instance, that due to Bothriocephalus and Ankylostomum, the field of pernicious anemia being thus restricted to those cryptogenetic or occult cases the primary cause of which we now had to look for.

Now a new factor was introduced by the theories of Ehrlich, who first considered pernicious anemia a specific disease, later, however, a specific reaction of the bone marrow, characterized by a retrogression of blood formation into embryonal megaloblasty. Consequently he assumed a definite blood picture characterized by macrocytosis. In spite of the argument of the various opponents of Ehrlich's conception concerning the significance of the megaloblasts, the advocates of Ehrlich's theory went so far as not only to maintain it, but even to amplify it, inasmuch as they assumed that only such cases of severe anemia could be looked upon as true or genuine pernicious anemia which exhibited intra vitam a macrocytosis of the blood and post mortem megaloblastosis of the marrow.

Disregarding the fact that neither the megalocytic condition of the blood nor the megaloblastic condition of the marrow can hold ground against an objective criticism, the question arises how those fatal cases of cryptogenetic anemia should be classified which do not show these signs in the blood and in the marrow; cases that no doubt occur very frequently and do not at all show the typical course of pernicious anemia. An answer to this question has not yet been given by the advocates of Ehrlich's theory. On the other hand, it gives rise to an entirely unjustified dualism which, while emphasizing the macrocytic types as true or essential pernicious anemia in contradistinction to the other types, causes about the same confusion as formerly was the case with the so-called true and false pseudoleucemia.

The advocates of Ehrlich's theory object to the older definition that in this a negative criterion is applied; that is to say, the absence of an organic finding gives the definition of the disease. This is, however, unhesitatingly accepted in other domains of pathology, for example, in the teaching of diabetes, in which formerly anatomical lesions were not at all known, and even nowadays etiologically different conditions are recognized, without any doubt existing with what is to be understood as diabetes. According to my view, the difficulty of discriminating between pernicious anemia and symptomatic anemia is not greater than separating diabetes from glycosuria. We need only to keep away from assuming a dogmatic standpoint and separating such cases in which anatomical alterations occur as true or genuine anemia; just as nobody ever thinks of separating pancreatic diabetes, as a true diabetes, from other forms, simply because in the latter no anatomical lesions are demonstrable. It is therefore by all means wrong to introduce into the clinically uniform picture a separation into different groups on the basis of certain reactions of the bone marrow.

On the other hand, we must object to the tendency of designating pathological conditions as pernicious anemia which undoubtedly do not belong to this group. I have noticed in numerous patients, who were sent to me in the course of years in a very distressing condition with the diagnosis of pernicious anemia, that this term is often used for entirely unlike conditions. In the majority of these patients I was not able to agree with the assumption that a severe degeneration of the blood was the chief feature of the affection. Moreover, we had to deal with pathological pictures, exhibiting besides a progressive cachexia an anemia of a medium severity with two or three millions of red blood corpuscles per c.mm., and even cases in which these cells showed no degenerative changes whatever and a rather increased content of hemoglobin. Even when death ensued an abundance of hemoglobin was present and consequently the exitus could not be ascribed to the anemia as such.

I have described these diseases in a treatise on organic marasmus that has appeared recently, and I have traced back their origin to functional disturbances of organs, offering at the first glance some analogy to pernicious anemia, but being explained on more careful analysis in quite a different way. I have explained in this work and illustrated by examples how by an increased or a diminished organic function for example of the muscles, of the kidneys, of the spleen, marasmic conditions may

*Read at a meeting of the New York Academy of Medicine, October 6, 1910.

arise which have to be considered as the result on the one hand of cellular hyperfunction, and on the other hand of a loss of function, as in cachexia due to the extirpation of the thyroid. All these marasmic conditions must be carefully separated by clinical investigation from pernicious anemia, the more so as the recognition of these conditions gives at the same time the most valuable indications for the treatment.

Another difficulty has finally arisen in the definition of pernicious anemia by the fact that a false appreciation of persons and names has become general, which, as a brief historical survey shows, is by no means justified.

In general up to a short time ago not only among German, but also among foreign authors, the view prevailed that the modern teaching of pernicious anemia was to be traced back to Biermer, who in 1868 and 1872 had published noteworthy lectures on this affection. Now W. Hunter has recently claimed the discovery of this disease for English authors, and quotes as the first author Combe, who in 1822 described a case of anemia, exhibiting all the phenomena of pernicious anemia, and being unable to discover at the post mortem a primary cause of the anemia, established at once a special classification for this case. Of greater significance were the descriptions published by Thomas Addison in 1855 as an introduction to idiopathic anemia in his famous work on the diseases of the suprarenal. Addison described here the general clinical phenomena of pernicious anemia in an excellent way, and emphasized especially that these conditions were to be traced back neither to loss of blood, nor to exhaustive diarrhea, nor to chlorosis or other organic diseases, and he proposed the term idiopathic anemia in contradistinction to the symptomatic severe anemia in consequence of other diseases. It is furthermore noteworthy that this author on the ground of autopsies already emphasized the absence of primary organic lesions, but was the first to describe the fatty degeneration of the heart muscle.

It is surprising that this correct description at first attracted little attention, although it was published in a work that was the starting point of the so extremely important researches on the affections of the suprarenals. Likewise the publications of the French author, Cazenave, in 1860, who described the disease as essential anemia, and of the German author, Lebert, were scarcely noticed.

Why the publications of Biermer in 1868 were so fertile can scarcely be ascertained to-day. At any rate, in the beginning of the seventies extraordinary work was started in this domain, and particularly the excellent monograph of Eichhorst in the year 1878 summarized in an objective way all the observations that had appeared up to that time.

How strong the influence of Biermer's publications was can be seen best from the fact that the above mentioned terms, "idiopathic" or "essential" anemia were mostly agreed upon even by English and French authors and in the entire international literature Biermer's term "pernicious anemia" was accepted. It is therefore not surprising that the influence of Biermer's work was overestimated, especially in Germany, and that consequently the affection was simply designated as Biermer's anemia. But it must be emphasized that although Biermer had given an excellent clinical description of the affection, his etiological conception was not quite clear, inasmuch as he for a number of these cases assumed no organic lesions as the cause, while he on the other hand considered intestinal ulcers for example a probable factor. In contradistinction to this, Immermann and Eichhorst in agreement with the view of Addison declared that only cases of anemia without demonstrable organic lesions were to be designated as pernicious. Later from 1885-88 William Hunter pointed to an intestinal etiology of anemia through an infection of the gastrointestinal canal with reabsorption of toxic products, by which for the first time a hemolytic injury of the blood without macroparasitical effects was proven. At about the same time the above mentioned theory of Ehrlich originated, who first traced back pernicious anemia to a primary affection of the bone marrow and later to a specific embryonal reaction of the marrow, due to a toxic cause.

If one would designate pernicious anemia after this historical sketch, according to one of these authors, it would be most correct to term it Addison's anemia since this author undoubtedly has given the most proper definition of this disease; however, in recent times William Hunter has claimed the term Addison's anemia for a peculiar infectious disease of the entire digestive tract with a consecutive very severe anemia, and thus it would not be justifiable to introduce this term for all types of pernicious anemia. The term Biermer's anemia is for that reason not correct, because Biermer placed also secondary anemias in this group, and just as little can we accept the term Ehrlich's or even Biermer-Ehrlich's anemia, because the strict limitation of severe anemia to a primary disease of the bone marrow can in the first place not be assumed and secondly cannot be brought in accordance with the conception of Biermer.

In order to obtain an exact definition of pernicious anemia it is at first necessary to say a few words about the clinical picture of this disease. As we know, this affection develops sometimes at an early age, mostly in the middle years of life, especially frequently in women. In its full development it offers the picture of a high degree of pallor, with a grayish shade, a high degree of general mental and bodily weakness, frequently accompanied by psychical anomalies of various forms. It is noteworthy that neither the muscles nor the fatty tissue are usually much impaired. As the most important signs are furthermore to be emphasized hemorrhages of the retina, dilatation of the heart with systolic murmurs, loss of appetite, constipation and in the majority of cases a lack of free hydrochloric acid in the stomach. At the same time there is usually a moderate increase of temperature and in advanced cases edematous swellings. These findings are above all characterized by the fact that a directly depleting organic disease is not demonstrable, and for the diagnosis our first object must always be to exclude by a thorough examination of all organs the presence of carcinoma or intestinal parasites.

The blood findings are of the greatest significance, and the question arises whether they are to be regarded as indicative of pernicious anemia. The most remarkable feature of the blood is the considerable lowering of the number of red blood corpuscles, which may sink far below one million, correspondingly a decrease of the specific gravity and of the dry weight, so that the blood appears

rather watery, and a strong decrease of the coagulability. With reference to the pathology of the red blood corpuscles the following striking difference in the statements of the authors has been found in the course of the last years. Since Quinke's investigations (1876) the prevalence of poikilocytes among the small and even smallest derivatives of blood cells was considered a noteworthy phenomenon in pernicious anemia, and my own former descriptions and pictures of such poikilocytic blood preparations were also generally regarded as correct. Recently, however, the opinion has been spread that the red blood corpuscles in pernicious anemia, to be sure, showed slight differences in shape, but otherwise were abnormally rich in hemoglobin and abnormally large. These statements are in a direct relationship to Ehrlich's theory of the megaloblastic reaction of the bone marrow, in the course of which abnormally large blood cells are also formed. An extreme instance of such a megalocytic blood finding is shown by an illustration in Naegeli's work, who found in pernicious anemia almost solely large, remarkably deeply colored red blood corpuscles, and designated this blood picture as the true type of pernicious anemia. From my own experience in several hundred most severe cases, partly confirmed by post mortem findings, I must confess that I have never seen in pernicious anemia such a blood picture with a total amount of about one and one-half millions of red cells. My experience is not confined to cases in the district of Berlin, but I have also had abundant opportunity to observe such patients from the many different countries. But I have never obtained blood preparations from patients of this kind in which the vast majority of red cells were of a normal or more than normal size with a content of hemoglobin exceeding the normal. It can therefore not be due to the locality that these blood pictures have not yet occurred to me in pernicious anemia.

In order to get an exact picture of the size of the cells, one must take pains in examining many series of fields with the micrometer, as Schaumann formerly did very exactly in bothriocephalus anemia. In order to avoid such rough estimations, I myself have had such countings done in a number of pronounced cases of pernicious anemia, and I have found that about 30 per cent. of the cells belong to the small forms up to 4.5 micromillimeters, about 60 per cent. to the medium sized forms of 4.5-7 micromillimeters, and about 10 per cent. to the large forms. Consequently there cannot be any question of macrocytic blood, and the authors who lay so much stress upon macrocytosis should not avoid the trouble of such a counting. Perhaps in reckoning by exact figures their general statements about macrocytosis would be modified.

It is noteworthy that Schaumann found in his investigations per 100 blood cells of healthy persons 1 small, 66 medium-sized and 33 large cells. In pernicious anemia, however, the average is 17 small, 32 middle-sized and 51 large cells. Just as Schaumann's exact investigations are by some authors pointed to as a proof of macrocytosis of the pernicious anemic blood, I wish to emphasize that the numerical deviation concerning the small cells (17 instead of 1 per cent.) is just as large as that concerning the large cells (51 instead of 31 per cent.), and, according to this, one would be just as right to speak of a microcytic blood picture as of a macrocytic picture. Undoubtedly in the blood picture of pernicious anemia some macrocytic forms are striking. However, these do not give to the blood picture the characteristic appearance, but the most marked feature is, in accordance with the nature of the whole disease, the exquisitely degenerative character of the morphological phenomena. Therefore I designate the blood finding as "erythro-degenerative," it being understood that a varying percentage of regenerative forms is at the same time present in the blood, as in every anemia, as a reaction to the injurious effect on the blood. The erythro-degenerative blood finding is not only according to my material, but also according to most authors in literature the most frequent blood finding, since even authors who emphasize the occurrence of megalocytes as important almost always report also the presence of marked poikilocytosis.

I should like to emphasize that I have observed a macrocytic blood finding without severe morphological changes in those grave anemias and cachexias which I have separated previously as an organic marasmus from true pernicious anemia. I think therefore that many a case of pretended pernicious anemia rather belongs to the group of anemizing organic diseases of various kinds.

The occurrence of megaloblasts was, as we know, also regarded by Ehrlich as characteristic of the blood finding in pernicious anemia. But in the course of years so numerous observations have been made concerning the occurrence of these cells in other cases of severe anemia that this assumption can no more be sustained. Moreover, the megaloblasts have to be regarded solely as a sign of the severity of the anemia, but not of the type of anemia.

Likewise I cannot consider the statement correct that the hemoglobin content of the blood is proportionately high as compared to the number of red blood corpuscles, as on the one hand the source of errors of the hemoglobinometer in these severe types of anemia is by far too large to allow the hemoglobin values to be directly referred to the numerical value of the cells. The figures themselves, however, are very hard to be determined, since only the developed cells, but not the smallest poikilocytes and cell fragments, are counted, which undoubtedly also contain hemoglobin. Consequently, of course, an incongruity must arise between the cell and the hemoglobin value, since for the small number of cells all the amount of hemoglobin is taken in account which is contained in the small cellular fragments. More important than this pretended hypernormal content of hemoglobin is the marked dissimilarity of the content of hemoglobin of the individual cells, which becomes manifest in even simply stained preparations.

According to this, I must answer negatively the question whether there is a blood finding specific for pernicious anemia and whether consequently the diagnosis of pernicious anemia can be made from the examination of the blood itself, since, as a matter of fact, all the same severe degenerative and regenerative types of blood formation are equally well found in other most severe forms of anemia; for example, in carcinosis. One might rather consider the findings in the leucocytes and the blood plasma characteristic since the leucocytes at the acme of the disease are always very much decreased, and the plasma, in contradistinction to carcinosis-anemia, for example, shows a proportionately high content of albumin, which points to

the fact that no general injury of the plasma is present here, but only a very specific injury, involving the red blood corpuscles. The small proportion of leucocytes is of an especial significance for that reason, because it has been found lately that the blood picture of pernicious anemia may also be produced by a leucocytic, especially lymphadenoid proliferation of the bone marrow. This gives rise to pathological pictures, which are on the one hand characterized by a high degree of diminution and degeneration of the red blood corpuscles and on the other hand by an increased invasion of typical lymphoid cells, until finally a mixed blood picture results, which, as we know, has been designated by Leube as leucanemic.

If we ask now whether pernicious anemia can be explained by the post-mortem findings, there can be no doubt but that the fatty degeneration of the heart muscle, the various hemorrhages, and also the lymphoid metaplasia of the bone marrow, which are the most frequent post-mortem findings, cannot be regarded as the primary causes of the grave blood affection, and just as little the atrophic alterations of the gastrointestinal mucosa, which, according to recent researches, are apparently found relatively seldom. Of quite a different aspect is the question whether the megaloblastic metaplasia of the bone marrow is to be considered a particular embryonal type of regeneration, specific for pernicious anemia, though not the only primary affection. According to my own numerous observations, and after studying the literature, I have come to the conclusion that as a matter of fact in a part of these cases a considerable prevalence of megaloblasts in the marrow is present, whereas in others not more of such cells occur than in any healthy marrow, and that again in other cases the lymphoid metaplasia may be absent entirely. Since also these latter forms are undoubtedly to be considered cases of pernicious anemia, they are a problem hard to be solved for those authors who regard megaloblastic metaplasia of the marrow as an essential criterion of the affection, and they have consequently overcome this difficulty by separating a special form of aplastic anemia.

This teaching of aplastic anemia as a particular morbid form is based upon the view that anemia is caused by aplasia of the bone marrow. I cannot at all agree with this view, as it is entirely incomprehensible how by a purely passive inactivity of certain parts of the bone marrow an anemia should arise. Moreover, I accept the opinion of Aubertin, Pappenheim, and others who do not consider these cases of anemia due to aplasia, but anemia with aplasia; that is to say, they regard it as a merely regenerative type of any kind of anemia. At the same time I wish to remark that I do not consider a diagnosis of these forms during life possible from the blood findings, which are supposed to show a diminution of erythrocytes and also of the hemoglobin. For I have often convinced myself that in such cases of pernicious anemia in which the entirely unsuccessful therapy suggested an aplasia of the marrow, a complete red lymphoid metaplasia of the marrow with copious erythroblasts is found post mortem.

Whoever considers the alterations of the bone marrow as exclusively varying degrees of reparative reactions of the blood matrix will see in the various findings in the marrow only the valuable fact that in one case perhaps all the long bones have undergone a lymphoid metaplasia, and that consequently the reparative action is developed up to a maximum. A great abundance of megaloblasts would then only indicate an excessive and accelerated regeneration. In another case one finds only a more intense lymphoid development in some districts of the long bones and consequently but a slight reactive process. Finally in other cases an aplasia is found; that is to say, a complete failure of the reaction.

From all these observations I come to the conclusion that the old definition is still nowadays correct, and that we therefore have to understand under the term of pernicious anemia such very grave forms of anemia as arise without any recognizable organic affection and without parasitic influence, as the result of a specific injury involving the red blood corpuscles.

From this it follows that the etiology of pernicious anemia can be cleared up only by clinical observations, and I think that we have to consider the following principal causes:

1. Pernicious anemia may originate from chronic loss of blood and a gradually developing insufficiency of the marrow. However, the majority of such cases are not to be regarded as pure pernicious anemia, as the diseases bringing about hemorrhages may exert a various and unexpected influence in the origin of anemia. The chronic hemorrhages due to gastric ulcers, for example, must be eliminated, as well as chronic hemorrhages due to myoma, since in the former the influence of the ulcers themselves, the passage of the blood through the gut, and in the latter the specific action of the myoma play a great part in the origin of anemia. Consequently we can only regard such cases as pure posthemorrhagic pernicious anemia, which originate from chronic hemorrhoidal hemorrhage or from epistaxis, unless even in these cases complicated organic diseases are not present.

2. Toxic substances, such as lead, arsenic, carbonic oxide, perhaps also morphine in chronic use, cause an anemia by a continuous injury of the red cells and finally lead to pernicious anemia. There are, however, surely also cases in which toxins of an unknown nature are effective.

3. Also hygienic errors, such as unsanitary dwellings, mode of life, and profession, may apparently cause such severe forms of anemia.

4. As the most important, and, according to my experience, most frequent cause I regard intestinal intoxications, which Hunter first explained as an infection of the gastrointestinal canal by inflammatory processes with the formation of bacterial products, which are supposed to cause a hemolysis after their absorption in the portal vein area. According to my view, we have not to deal with an infection, but with an intoxication; I think that in all these patients a primary lack of free hydrochloric acid in the stomach plays an important part. Owing to this fact toxic substances in the ingested albuminous stuffs may be formed in the following way: I wish to state first that this theory is based upon the picture of intestinal intoxication offered by bothriocephalus-anemia, in which, according to the researches of Schaumann, Rosenquist, Talquist, a hemolytic poison is formed in the intestine which causes severe anemia after absorption. Talquist has recently designated oleic acid as such a poison and also in pernicious anemia not due to bothriocephalus-lipoid substances are said to be formed in the gastrointestinal mucosa which have a hemolytic effect. According to the present stage of re-

searches I cannot agree that the proof has been given of the sure existence of a specific lipoid in pernicious anemia, since also in healthy individuals such substances can be extracted from the intestinal mucosa with a more or less high degree of hemolytic power. Moreover, my view concerning the origin of grave anemia, owing to a lack of hydrochloric acid in the stomach and perhaps to enteric disorders, is as follows:

a. We must take in account the failure of the disinfecting action of hydrochloric acid in the stomach, which plays a particularly important rôle, if, for example, pathogenic microorganisms from carious teeth or other parts of the mouth, especially pus-bacteria, are swallowed. They find a good culture medium in the albuminous substances of the ingesta without being hindered in their development by the influence of hydrochloric acid. Toxic substances, developing on account of such infections during the passage through the small intestine might, above all, be looked upon as a hemolyzing factor.

b. We must, however, consider that with an absence of hydrochloric acid and a lack of gastric digestion the breaking down of the albuminous molecule may be so far impaired that the physiological end-products of albuminous decomposition are not formed and absorbed, but that the transformation of the albuminous molecule remains in an intermediate stage, and that these substances on absorption are able to act toxically.

c. However, another factor comes into consideration which results from recent investigations on anaphylaxia, *id est* on toxic effects from repeated injection of heterogenous albumin. It has been shown that not only after a subcutaneous or intravenous injection of heterogenous albumin a hypersensitiveness to it occurs, but, according to the investigations of Rosenau and Anderson, of Börnstein, and others, these toxic phenomena also occur after feeding heterogenous albumin. By this Römer's view, pronounced some years ago, is confirmed that digestion has the important function of depriving the heterogenous albumin of its property of producing antibodies. Although by boiling the food the specific action of the heterogenous albumin is partly eliminated, yet everybody takes in such large amounts of uncooked heterogenous albumin that phenomena of anaphylaxis would necessarily occur, if the breaking down of this albumin were not sufficiently accomplished by the peptic processes, especially in the stomach. Thus in a functional disturbance of the gastric secretion toxic injuries can be produced either by the influence of bacteria, or by a faulty breaking down of albumin, or by a deficient transformation of the heterogenous albumin. By these toxic substances we can explain the peculiar and specific injury involving the red blood corpuscles in a similar way, as the absorption of the toxic products of *Bothriocephalus latus*.

That this theory really holds good in many cases can be proven by the results of therapy in a great number of cases of pernicious anemia, just as it is done in a similar way in *Bothriocephalus latus*, by expelling the worm.

In entering now into the treatment of these affections, I emphasize from the very beginning that a rational therapy can be undertaken only when (1) most accurate and repeated clinical investigations have established the absence of an organic affection or the presence of a parasite, and when (2) by a thorough consideration of the anamnesis and particularly of the condition of the gastrointestinal canal it can be decided through what injury the individual case of pernicious anemia may have arisen.

In the first place we shall have to think of the effect of some known poisons, as lead, arsenic, morphine; furthermore, of the existence of hemorrhages of the above described kind. And, of course, in these cases the injurious cause will have to be removed first of all.

In the great majority of cases observed by me we had to deal, as I said, with intestinal intoxication. In the course of years I have worked out a treatment on the basis of these considerations. This therapy is in the main dietetic, and is carried out by ingesting on the one hand no animal albumin, which is to be regarded above all as a source of toxin-formation, and secondly, trying to prevent a decomposition of the foodstuffs. The first point of this treatment is accomplished by giving these patients at first exclusively carbohydrates and fats in the most digestible form, vegetables, fruits, soups, and at the same time foodstuffs which stimulate the appetite, avoiding however meat and eggs entirely. If these patients are in a high degree of exhaustion we may give substances very rich in albumin, as in nutritive enemas, eliminating thereby the abovementioned dangers. The second way of disinfecting is at the beginning the best—regular lavage of the stomach with a one to two per cent. sodium chloride solution, and at the same time a daily irrigation of the gut, likewise with a solution of sodium chloride, by which, as I think, the mucosa is best and most safely cleansed, and at the same time stimulated. If the patients are too weak to bear the lavage of the stomach we must restrict the treatment to ingesting fresh juices of fruits, best lemonjuice in form of lemonades, thus supplying a certain substitute for the lack of hydrochloric acid in the stomach. This is the same treatment that has been applied for scurvy, which depends undoubtedly also upon a putrefaction of albumin. I do not consider the use of disinfectants, such as calomel, indicated in these patients. If the patients are very exhausted alcoholic drinks may be allowed. Special attention has to be directed to the condition of the always affected heart-muscle, and therefore it is best to administer digitalis preparations from the very beginning. Of course, the patients must, at first, be confined to bed.

The usual course is now that solely under this dietetic and strengthening treatment the temperature, which is always increased at the beginning, goes down, the appetite, being usually entirely absent, begins to come back, and the patients feel better. At this time I begin then the arsenic treatment, which I carry out by injecting a neutral one per cent. solution of sodium-arsenate in increasing doses from 1 milligram to 1 centigram daily. I am not able to state that the newer organic arsenic preparations give better results in these blood diseases, and the application of inorganic preparations offers the advantage that the toxic symptoms are known and can easily be recognized, while the organic preparations, especially atoxyl, as we know, in not a few cases lead to the most severe symptoms of intoxication, especially to blindness.

Iron is of no use in the treatment of these forms of anemia, if we consider that the patients must have large iron-deposits in the liver, on account of the strong hemolysis, which they can use sufficiently

as a material for building up hemoglobin. The treatment with organic preparations made of bone-marrow has, as far as I can see, given no particular results, and I think it does not offer any chance if we consider the peculiar etiology of these affections.

Transfusions of human blood are, however, important. In some cases they have been done successfully in patients in whom the regeneration of the blood was extremely poor. But it has been recently shown in my laboratory by Werner Schultz in extensive researches, that before carrying out any transfusion the action of the blood of the donor upon that of the recipient ought to be tested carefully with respect to the hemolysing and agglutinating power. I warn, therefore, against performing transfusions without these important precautions.

Finally, I wish to emphasize that, of course, this particular treatment of the intestinal tract cannot be successful in all cases, since in the first place not all cases of anemia originate in the same way, and secondly, the capacity of regeneration of the bone-marrow is an uncertain factor, which can not even approximately be taken into account beforehand. The prognosis is therefore to be considered doubtful in every case. If, however, a favorable result has been obtained by this treatment we have no reason to doubt that this result is a permanent one. Various authors have very correctly pointed out that relapses occur frequently in this affection. These relapses, however, can be explained in just as simple a manner as those in diabetics who have been made free from sugar by a rational diet, in whom, however, the disease appears again after a more copious ingestion of carbohydrates. In the same way the patient with an insufficient gastric secretion is again exposed to the danger of the effect of toxic products if his mode of life becomes irregular, and he eats eggs and indigestible albuminous stuffs; for a complete restoration of the gastric secretion has scarcely ever been observed even in apparently entirely cured cases. It is, therefore, by all means necessary to supply the patient, as soon as he is dismissed as cured, with strict dietetic prescriptions, and in this way we succeed in obtaining not only a transitory but a really permanent recovery.

Gentlemen: I have tried in the limited time I had for this paper to outline the chief features of this affection. Should I have succeeded in attracting your attention to this subject, clinically so very difficult as well as important, I feel that the purpose of my lecture is attained.

SUPPURATION OF THE ANTRUM OF HIGHMORE.*

By WALTER A. WELLS, M.D.,

WASHINGTON, D. C.

PROFESSOR LARYNGOLOGY AND OTOLOGY, GEORGETOWN UNIVERSITY, SURGEON IN CHARGE DEPARTMENT THROAT AND EAR DISEASES, GARFIELD HOSPITAL.

SURROUNDING the nasal passages, and hollowed out of the adjacent bones of the face and skull, we have a regular series of pneumatic cells generally spoken of as nasal accessory sinuses. These cells, or sinuses, are in direct communication with the nose by constant and definitely situated mouths, or canals, through which the mucous membrane of the nose becomes directly continuous with the lining of the interior of the sinuses. As it is natural to expect, the accessory sinuses will partake more or less of the inflammatory processes which attack the nose, and recently we have come to understand that many of the symptoms and much of the suffering which formerly were attributed to the inflammation merely of the nasal membranes are really to be ascribed to the involvement of these neighboring air cells. Being residnal organs, the sinuses have less resisting power than parts with active normal functions, for which reason they are prone to fall prey to disease, and, owing to their character and confirmation, inflammations here tend to assume a suppurative type, terminating in abscesses or empyemata. The maxillary, or, as it is called, the antrum of Highmore, is the largest of the accessory sinuses; and it is also the most frequently affected and the most accessible to treatment. We have selected it, therefore, as of all the one most interesting and profitable to discuss before a body of general practitioners.

Surgical Anatomy.—The antrum of Highmore is a somewhat pyramidal-shaped cavity, hollowed out of the body of the superior maxilla. The base of the pyramid is constituted by the outer wall of the nose; the apex is directed toward the malar bone. The roof of the antrum is identical with the floor of the orbit, while its own floor corresponds with the alveolar border of the jaw, and is separated from the roots of the bicuspid and molar teeth by a plate of varying thickness. In many cases the latter is so thin that the roots of these teeth, when diseased, very readily penetrate and thus infect the cavity. It is estimated that about 50 per cent. of all cases of suppuration of the antrum are of dental origin, which explains the frequency of antral diseases as compared to diseases of the other accessory sinuses. The large size and forward situation of the antrum, and especially the fact that it has one entire wall, for the most part thin and membranous in relation with the nasal cavity; and that the floor is in relation with the teeth, and that, finally, it has a third wall which may be surgically attacked presenting in the canine fossa make it the most approachable of all the nasal sinuses.

An anatomical peculiarity of the maxillary sinuses which has an important bearing both upon pathology and treatment is the situation of its ostium. Instead of being at the most dependent point and therefore in the best situation for drainage—as we observe in the case of the frontal sinuses—the maxillary ostium is, on the contrary, in the uppermost part of the nasal maxillary wall and close to the roof, in a situation which is, as is readily understood, the most unfavorable for drainage. The movement of the cilia under normal conditions probably has the power of conducting the secretions toward this ostium and so into the nasal cavity, but the presence of pus and a generally diseased condition of the mucosa hamper the action of the cilia so that such an effect is impossible. Under such conditions the cavity must fill to the top before the secretions can escape, and stagnation is the unavoidable consequence.

Classification.—Suppuration of Highmore's antrum may be due to three different conditions: (1) Empyema, (2) Acute Maxillary Sinusitis, (3) Chronic Maxillary Sinusitis.

Empyema.—By empyema of the antrum of Highmore we mean strictly the mere presence of pus, which has arisen not from inflammation of the antrum itself, but has overflown from a neighboring

*Read before the Georgetown University Medical Society, April 12, 1910.

cavity, as the ethmoid or frontal. The situation of the antrum below these cavities is such that it may sometimes act as a reservoir for the pus originating in one or both of them; and, as explained, the pus, being unable to escape, must remain stagnant, eventually becoming stale, and, it may be, foul smelling. An abscess of the root of the tooth may give rise to this condition, and an exceedingly foul-smelling discharge is thought to be a point in favor of its dental origin.

Acute Inflammation.—Suppuration due to acute maxillary sinusitis occurs more often as a complication of grippe than from any other cause. Inasmuch as it is seldom that one accessory sinus becomes inflamed to the exclusion of all the others, we cannot depend for the diagnosis upon the location of the pain. While a maxillary sinusitis should produce a pain especially in the malar region, this may easily be overshadowed by a severe orbital, frontal, or occipital pain due to a contemporaneous involvement of the frontal, ethmoidal, or sphenoidal cavities. If, however, we find tenderness in the area just below the orbit, and toothache on the corresponding side, we may say that the maxillary is at least one of the cavities involved. That the inflammation is of a suppurative type we judge from the character of the discharge coming from the affected side of the nose. A thick, yellowish, gelatinous, or creamy—in the case of grippe sanguinolent—discharge of greater abundance than we should expect from an ordinary rhinitis—should excite a suspicion of sinus involvement. If coming from one side only of the nose this is also strong presumptive evidence in favor of the sinus origin.

Chronic Inflammation.—On account of the absence of pain and other acute symptoms, the existence of a chronic suppurative maxillary sinusitis is much more likely to be overlooked than the acute. In many instances the patients are unable to give any history of a preceding acute attack and they attribute the continuous discharge of secretions from the nose to an ordinary nasal catarrh. In addition to having in common with acute sinusitis a more or less purulent unilateral discharge, patients with a chronic form of the trouble are apt to present another symptom, characteristic of a long-standing suppuration of the maxillary antrum, namely, cacosmia. Disagreeable odors, it is to be noted, are subjective as well as objective; in fact, it is often perceived by the patient and remarked upon, when it is not clearly perceptible to others. This is precisely the reverse of the ozena of atrophic rhinitis, which, though horribly offensive to others, may be entirely unknown to the unfortunate subject on account of the always accompanying atrophy of the ends of the olfactory nerve. In cases of chronic antral suppuration this subjective cacosmia is sometimes the only symptom of which the patient complains, and when mentioned, it should invariably suggest to the physician such a causation and induce him to explore the sinus for the presence of pus.

Diagnosis.—To determine definitely whether or not the antrum is the seat of suppuration we must make a careful examination of the nasal passages, and apply certain well-established tests. Pus seen in the middle meatus in the region of the hiatus semilunaris may have its origin in either the antrum, the frontal sinus, or the anterior ethmoidal cells. The situation of the *ostium maxillare* at the upper part of the cavity enables us to apply a test which, when positive, is quite conclusive of antral suppuration. Having first thoroughly cleansed the nasal passages with some simple saline solution, and then applied a little cocaine or adrenalin in the region of the meatus to contract the tissues and assure a patent ostium, we direct the patient to flex the head to such a degree that the opening is brought into a dependent position. If a quantity of purulent secretion then makes its escape it can only be from the maxillary sinus.

Another test, which, notwithstanding all the adverse criticism which has been directed against it, must still be regarded as a very valuable diagnostic aid is transillumination. If a light placed in the mouth fails to illuminate a crescentic area just below the eyelid upon the suspected side—while upon the other side it appears in its normal intensity—this fact, although not conclusive evidence, gives a presumption in favor of maxillary disease sufficiently strong to justify making at once an exploratory puncture. If, on the other hand, both sides illuminate normally and a light appears in the pupils, objectively or subjectively, we are safe in excluding the supposition of an antrum filled with pus. The transillumination test is therefore one which should constitute an indispensable part of the routine examination. But to determine conclusively the presence or absence of pus, we must resort finally to the exploratory puncture. A fine trocar and cannula are introduced through the wall of the inferior meatus and the cavity irrigated with some bland antiseptic solution. The fluid will return clear if the cavity is healthy; if diseased, it will be cloudy, more or less loaded with flakes or masses of yellowish or greenish matter, at times very fetid.

Treatment.—The treatment of maxillary sinus suppuration can (conjointly with that of the other nasal accessory sinuses) be comprised under the following three indications, viz.:

(1) Remove the products of the inflammatory process which may be only pus, or may be degenerated or polypoid mucosa, or may finally be carious bone.

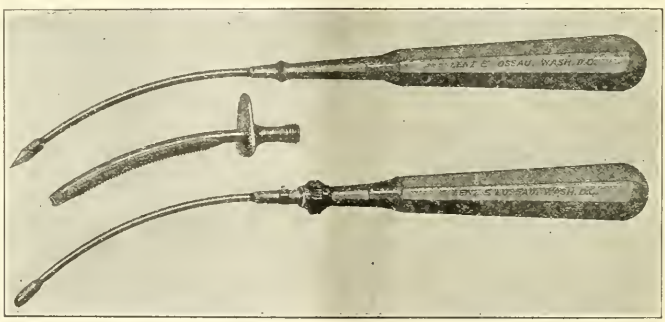
(2) Provide drainage.

(3) Establish ventilation.

If it were possible *a priori* to judge from the clinical symptoms which the patient exhibits, or from the objective signs which by our examination we may elicit, the exact pathological state of a diseased sinus, we might, from the above indications, easily deduce a formula and establish a logical mode of procedure for any given case. This would be, namely: In empyema and acute inflammation, wash out the pus; in chronic inflammation, so expose the cavity as to be able to remove respectively polyps, granulations, degenerated mucosa; or, it may be, carious bone or sequestra. In all cases, do whatever may be necessary to establish a full communication between the antrum and the nasal fossa, thus assuring satisfactory ventilation and drainage. Unfortunately, we cannot by any means other than by the examination of the interior of the sinus definitely ascertain the exact pathological state which may exist. The fetor of the secretion is not, we know, a dependable criterion, as often in such cases the mucosa is so little affected that we find the removal of the secretion alone is sufficient to permit a prompt return permanently to normal conditions. The presence of numerous polyps in the middle meatus might be regarded as favoring the idea of chronic disease of the sinus, but that is likewise a far from conclusive sign. The chronicity of the supparative process should be, if it were

a determinable factor, the most reliable guide for judging the state of the mucosa, and consequently in deciding upon the necessary operative procedure. As we have already stated, however, patients are singularly indefinite as to the beginning of their trouble; and we are often in the dark as to the duration of the disease. In the majority of cases we know that pus is present, but not how long it has been there. Still less are we able to say just what is the exact pathological state of the sinus mucosa. Under such circumstances conservative methods appear to my mind to be the rational ones. We should begin tentatively, apply first the most conservative step, and only upon the failure of this proceed to radical methods. A tentative method of procedure based upon a tentative diagnosis may be adopted according to the following formula:

A. Empyema: One should irrigate the antrum by means of a simple puncture through the inferior meatus. If the pus is draining into the antrum from a neighboring sinus, the indication, of course, is imperative to cure the affected sinus responsible, in order to prevent a reaccumulation of the pus. If a diseased tooth is at fault it should be extracted, and if the removal of the tooth makes a passage directly into the cavity irrigation may be practised through this route.



B. Acute maxillary sinusitis: One should irrigate the cavity as suggested for empyema; this failing, it may be necessary to make a wide artificial opening in the lower part of the nasoantral wall for ventilation.

C. Chronic maxillary sinusitis: One should make a wide artificial opening in nasoantral wall; this failing, one should expose the sinus through the facial wall and curette the interior.

Technique.—To make a simple irrigation of the sinus a fine trocar and cannula are used, and the puncture made in the inferior meatus, close under the attachment of the inferior turbinal, where the bone is thinnest. This procedure can be done quite painlessly under a local anesthetic. To make a large opening through the nasoantral wall it is necessary in most cases to remove the anterior part of the inferior turbinal. An artificial opening should then be made in the lowest part of the outer wall of the nose, close to its floor, as being the most favorable position for drainage. This opening can be utilized subsequently as a way for washing out the cavity, and often it will allow of a limited curettage of the antral cavity.

For making this opening I have found very satisfactory an instrument I devised several years ago, which consists of a trocar and cannula, the latter having upon its concave surface a cutting rasp. The nasoantral wall, having been pierced with the trocar, the latter is withdrawn, leaving the cannula in place. A blunt obturator is substituted and fastened by a thumbscrew to the rasp cannula and then with a to-and-fro motion the surrounding wall is cut away. This operation can ordinarily be performed under good local anesthesia, and requires but a few minutes. Finally, the state of the sinus being such that only a very thorough curettage will effect a cure, the sinus must be widely exposed in the region of the canine fossa. We may then, after cleaning out all diseased membrane or bone, pack with gauze and adopt the open wound method of treatment; or we may close the external wound and allow drainage to be conducted by way of the nose, through the establishment of a large communication artificially created in the nasoantral wall. I prefer the latter, which is known as the Caldwell-Luc procedure.

Whatever method may be adopted for the purpose of removing pathological products of disease found in the antrum, the other two indications must be constantly borne in mind and applied in all cases. To secure adequate ventilation and effective drainage will not infrequently require supplementary operations upon the nasal passages, when the main operation is done, or at some other time. For if we do not correct intranasal conditions, whether it be a deviated septum, a bulbous middle turbinal, a nasal spur or polyp which obstructs the outlet of the antrum, we leave behind conditions which will tend to reproduce the original trouble and so interfere with permanent recovery.

REMARKS ON THE TWENTIETH ANNIVERSARY OF THE AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.*

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

The President of this Association has been good enough to invite me with urgent cordiality to say something about the earlier work of my former associate, Dr. Geo. M. Beard, and myself along the line of electricity in medicine. In a way I hesitate to do anything of this kind, and in acceding, I beg you to remember in extenuation that many of you are no

*Read at the annual meeting of the American Electrotherapeutic Association, held at Saratoga, Sept. 14, 1910.

further from the beginning of an active professional career than I am from the end.

It was in 1868 or 1869, I believe, that my attention was first called to this subject. During my medical college course I do not remember to have once heard the word electricity in connection with the treatment of disease.

Medical journals seldom referred to it in any way, and of American contributions to the subject, with the exception of Garrett's ponderous and unphilosophical work, there was absolutely none. And so when I met an old man about that time who called himself an electrician, my interest was at once excited. He was an excellent example of perfect honesty, large experience, such as it was, and profound scientific ignorance. He had treated a multitude of people and was highly respected by Dr. Willard Parker and other prominent physicians who occasionally sent him patients.

And yet when I approached Dr. Parker, whom I well knew, and said to him that I thought of taking up the subject in a systematic and scientific way, he quickly replied: "Don't do it. Any old woman can apply electricity." Another equally eminent physician with whom I was on most friendly terms said: "do not ask me for the use of my name. You had better leave it in the hands of the quacks where it belongs." So it was evident that while both these excellent men believed somewhat in the virtues of electricity, they believed also that it was as simple an affair to administer as a hot or cold bath. The secret of this old man's success was, that in addition to his stereotyped yet most thorough and skilful method of application, he had at his command even at that time, a coil yielding a quality of current that has not since been surpassed, and far superior to many that are now in common use. About this time I renewed a former acquaintance with Dr. Beard, and to him I related my experience with this old man, and he in turn told me that while a student at Yale he had become interested in the subject and had frequently applied to himself the current from a small induction coil and with what seemed to him beneficial results. For several years this was the only kind of electricity, if I may so speak, at our command. No galvanic apparatus was then readily obtainable, and I well remember the disgust with which we resorted to the voltaic pile with its suffocating fumes, when that kind of electricity was wanted. No static electricity, no high frequency currents, no *x*-ray, no treatment by auto-conduction or auto-condensation, no light apparatus, only the simple faradic current, but when I recall the really excellent work that was done in those days I am impressed with the truth of Dr. Beard's aphorism, "that it is not so much electricity that cures as the method of using it."

It seems to me that this is a fitting time and place to offer a tribute to the memory of Dr. Beard. He has been dead many years, and if he could now witness the progress that has been made in the department in which his acute and original mind took such a deep interest, his astonishment would indeed be great.

He died at the early age of forty-three, when as someone said of him, "notoriety was beginning to merge itself into fame." As a clear, brilliant and rapid writer he was unsurpassed. He told his story with the facility and delightful felicity of a Macauley. No one subject could hold him long after it had ceased to interest him, or after he had taken from it all at the time he thought it capable of giving. In the earlier days of Mr. Edison's career he collaborated with him in investigating what at the time seemed to both of them a strange and mysterious manifestation of electricity which was termed etheric force. It led to nothing practical, but his clever and exhaustive discussion of the subject in the pages of the New York *Tribune* was a notable event. In the late seventies he coined the term neurasthenia and wrote his classic and memorable monograph on that subject. It is not too much to say that all the subsequent literature both here and abroad on neurasthenia is based on Beard's original investigations. Hypnotism and questions of psychic interest then engaged his ardent attention and keen discriminating examination, when presently he fell a victim to his all too strenuous and concentrated labors. His contributions to the subjects of seasickness and hay fever, his fascinating work on American nervousness, his valuable monograph on the legal responsibility of old age, with innumerable other contributions, all more or less original, forceful, and charming in tone, marked him as a worker and writer of an unusual order. What he would have achieved with a few more years of active work—who can say?

And now, Mr. President, a word in regard to our organization. Those of you who have read the interesting reminiscences of Mark Twain by his friend Mr. Howells, will recall that when the genial and philosophic humorist was asked "why men so disliked to talk much of the past," his reply was "because the past is so damned uncomplimentary."

I do not profess to know how it may be with the individual lives here to-night. Doubtless the past could reveal some uncomplimentary things about the best of us, but as it is not the individual life that we here commemorate, but the life of an association, our combined lives as related to the specific work of this society, we will let that pass. Personally I do not much believe in mutual admiration societies, for the man or thing most boisterously praised is often found most vulnerable under the cold, north light of impartial criticism. This society and its work will be judged by the great medical profession, not by what you and I say about it, but by the sum of its recorded activities, and as I recall the many views that have been advanced and the statements as to the specific therapeutic properties of the various physical agents, I am very much inclined to the opinion as to some of them, that Mark Twain's witticism would not be altogether misapplied.

Confession is as good for the soul of an association as for the soul of the individual.

It is not passing strange if in the pursuit of new objects and the exploration of untried fields enthusiasm sometimes overtops judgment.

The pioneer explorers of an unknown world saw many new and wonderful things, and the archives of their respective countries show that in recording their observations, fancy very often ran riot with fact. It was only after many years of repeated explorations and much sifting that the chaff was eliminated and the kernel or truth alone remained. As our strenuous ex-president remarks, "only the man who does nothing makes no mistakes." The same is true of any association of men, and therefore true of this association. It has done things and it has made mistakes.

Let me not be misunderstood. If in the past either as an organization or through individual contributions it seemed at times to tread the empirical,

rather than the true scientific path, yet upon the whole it has been commendably progressive, productive, and original, and if in its archives as in the archives of nations, are found here and there statements that it will be well to forget, let us charitably attribute them to temporary obsessions, excited by new and strange possessions.

Basing his antagonism to this society on what he thought he saw of evil rather than of good, a member of our profession, eminent, but certainly not broad-minded or kind, said that he would like to see it killed or die of inanition. To him I would apply the story of old Ludovicus Vives. The "story of the clown who had killed his ass because he had drunk up the moon, and he thought the world could ill spare that luminary. So he killed the ass ut lunam rederret.

The clown was well intentioned but unwise. Let us not imitate him. Let us not slay a faithful servant who has carried us far. He did not drink the moon, but only the reflection of the moon in his own poor water pail, where, too, he was drinking perhaps with the best intention."*

It would be unfortunate if, either as individuals or as an association, we should come to be regarded as special pleaders only. Let us beware of that. Let us not forget that we are physicians first and electro-therapeutists after, and while not abating one whit of our enthusiasm see to it that the judicial faculty be not subordinated to impulse and desire. Be true if you would be believed. With truth and genuine earnestness on your side, men must and will give heed to you. Let not the promise exceed the performance. Understate rather than overstate, for in so doing, the foundations you are now laying will become so strong, each stone in the structure so firmly set, that the superstructure will be an enduring monument to your honest and earnest endeavor.

616 Madison Avenue.

*Carlyle's Essay on Voltaire.

A CASE OF TYPHOID MENINGITIS.

By BENJAMIN SCHWARTZ, M.D.,

NEW YORK,

ASSOCIATE PATHOLOGIST TO THE GOUVERNEUR HOSPITAL, DEPARTMENT OF BELLEVUE AND ALLIED HOSPITALS.

Because of the rarity of this condition, I wish to report the following case of typhoid meningitis:

J. C., aged 8, male. Entered the Gouverneur Hospital, April 20, 1910. Family history was negative. Previous history: He has always been thin and anemic. He had measles at the age of seven. Present illness began two weeks ago with frontal headache and pain in the abdomen, soon followed by diarrhea, which became a very troublesome symptom, the patient passing as many as a dozen watery stools daily. He vomited frequently. Three days before admission he took to bed, and during this time his mind gradually became dulled. On admission the patient was in a somewhat stuporous condition, his temperature being 101°, soon, however, rising to 105°, his pulse 102, and his respirations 36. He was poorly nourished and developed. The skin was warm and dry, and no eruption was present. His pupils were dilated. His tongue was dry and heavily coated. The heart sounds were rapid, regular, and weak. The lungs were normal. The abdomen was retracted, not rigid or tender. The spleen was just palpable. The liver dullness was normal. The patellar reflexes were increased There was no Babinski, Kernig or rigidity of the neck. Urinary examination: Light amber, clear, acid, with faint trace of albumin, sugar absent, diazo reaction negative, no casts. Provisional diagnosis: typhoid fever.

April 21: the patient is very restless and irrational, restraint being necessary. Diarrhea continues. The temperature ranges between 103° and 104.8°, the pulse between 100 and 110, and the respirations between 30 and 36. April 22: the general condition is worse. The patient is irrational. Diarrhea continues. The temperature ranges between 101.2° and 102.8°, the pulse between 90 and 120, its quality being weak and irregular, and the respirations between 30 and 40. The Widal is negative. *Slight Kernig* is present. April 23: the patient is restless and irrational. The right pupil is wider than the left, both reacting sluggishly to light. Tache cerébrale is present. There is no rigidity of the neck. Diarrhea continues. The temperature ranges between 100.2° and 102.2°, the pulse between 100 and 130, the respirations between 44 and 48. The white blood cells numbered 10,000, with a differential polynuclear count of 72 per cent., and lymphocytes of 28 per cent. April 24: the patient continues to be restless and irrational. The temperature ranges between 101.2° and 102°, the pulse between 100 and 140, the respirations between 44 and 46. Harsh breath sounds and moist râles are heard over the right base posteriorly. April 25: the patient is in complete coma, passes urine and feces involuntarily. The neck is *slightly rigid*. The temperature ranges between 99.7° and 101.5°, the pulse between 132 and 144, the respirations between 32 and 56. The white blood cells numbered 24,400, with a differential polynuclear count of 68 per cent. and lymphocytes of 32 per cent. A lumbar puncture was performed, tubercular meningitis now being suspected on account of the predominance of the mental symptoms, slight Kernig and rigidity of the neck, the pupillary changes, the presence of pulmonary signs, leucocytosis, the negative Widal, and the absence of roseola. Twenty-five c.c. of a somewhat turbid fluid was obtained under great pressure. The patient died several hours after the subarachnoid space had been tapped. Unfortunately consent for a post-mortem examination was not obtained.

The examination of the spinal fluid was made three to four hours after withdrawal. Smears of the sediment showed the presence of very numerous Gram-negative bacilli, and markedly increased cellular elements. A careful differential count was not made, but there seemed to be a predominance of what appeared to be small lymphocytes. The benzidin test carefully controlled by a positive test with diluted blood was negative. A pure culture of *Bacillus typhosus* was obtained from the fluid. The microorganism was identified by the following characters: *Morphology*. A small and very actively motile Gram-negative bacillus. *Cultural Characters*. Milk was slightly acidified but not coagulated. There was no indol production in Dunham's peptone water. There was a slight growth on potato. Gelatin was not liquified. There was no gas in Hiss tube medium. There was acid production without gas in glucose and mannite serum water. There was no acid or gas production in saccharose or lactose serum water. *Agglutination*. The bacilli were agglutinated by the serum of a known typhoid patient in a half hour in a dilution of one to one hundred.

A meningitis existed in this case on account of

the presence of a large number of cellular elements and the typhoid bacilli in the cerebrospinal fluid.

The cases have been divided by Cole into cases of "meningism" cases of "serous meningitis," and cases of "suppurative meningitis," and the literature carefully analyzed from this point of view. Cases are excluded because of failure to isolate or properly identify the organism. In reviewing the literature I am surprised to find that no effort has been made to eliminate contamination from admixture of blood. Since the *Bacillus typhosus* is present in varying numbers in the circulating blood in practically all cases, this precaution seems to me essential. Many of the cases falling under the second group, "serous meningitis," are open to this suspicion. Thus of the cases cited by Cole, the following must remain unproven for this reason.

Case 1. Tictine: *Arch. de Med. Exp.*, 1894, VI, p. 1.

Case 2. Rocco-Jemma: Abstract given by Loeb, *Deutsches Arch. f. Klin. Med.* Bd. 62.

Case 3. Rocco-Jemma: *Gaz. degli osp. e della clin.*, 1897, XVIII, p. 1575.

Case 4. Boden: *Zeit. f. pract. Aerzte*, 1899, VIII, S. 233, also *Münchener med. Woch.*, 1899, XLVI, S. 303.

Case 6. Fernet et Lacapère: *Bull. et Mem. Soc. Med. des Hôp. de Paris*, 1900, XVII, p. 513.

Case 8. Weichardt: *Zeit. f. Hygiene u. Infectionskrankheiten*, 1901, Bd. XXXVI, S. 440.

Cases 9, 10, 11, 12, 13. Cole, *Johns Hopkins Hospital Reports*, 1904, XII, page 379-410.

The references to meningitis complicating typhoid fever published since the appearance of Cole's paper in 1904 are as follows: Under the first group are included ten cases of typhoid "meningism" in which, following Cole's classification, the diagnosis depended solely upon the clinical features, and was not confirmed by recovering the typhoid bacillus from the spinal fluid:

Huber: *Arch. Pediatrics*, 1904, V. 21, p. 1.

Achard & Paisseau: *Bull. et Mem. Soc. Med. d. Hôp. de Paris*, 1904, 3 s. V. 21, p. 329.

Staublii: *Deutsches Arch. f. klin Med. Leipzig*, 1904-5, V. 82, p. 90. Two cases.

Under the second group, the so-called "serous meningitis," there have been five cases:

Case I.—Schutz: 1905, *Berl. klin. Wochenschrift*, V. 42, p. 1465. Male, aged 20, entered the hospital March 6, on the ninth day of illness. Onset with headache, vomiting, rigidity of the neck, and fever. On admission headache was very severe and rigidity of the neck was present. Widal reaction was negative. March 6 to March 11, headache was a prominent symptom. March 11 a lumbar puncture was performed, 13 c.c. of clear fluid being obtained. No smear of the fluid was made. On culture *Bacillus typhosus* was obtained. March 18 the spleen was palpable and roseola were present. The Widal subsequently became positive. Patient recovered.

This case must be considered unsatisfactory, as contamination by blood had not been excluded.

Case II.—Schutz: *ibid.* Male, aged 38, entered the hospital March 12, on the ninth day of illness. Onset with headache, pains in extremities and fever. On admission headache was very severe, rigidity of the neck and petechiæ were present. March 14 a lumbar puncture was performed, 6 c.c. of clear fluid being obtained. No microscopic examination of the fluid was made. The culture showed the presence of *Bacillus typhosus*. *Bacillus typhosus* was obtained from the urine and feces the subsequent week. March 20 roseola present. Widal became positive during the decline of the temperature. Patient recovered.

This case is open to the same suspicion as the previous case.

Case III.—Silberberg: 1908, *Berl. klin. Wochenschrift*, V. 45, p. 1354. Male, entered the hospital on the fifteenth day of illness in a semicomatose condition. Complained of headache when aroused. Roseola and rigidity of the neck were present. Pupils were dilated. Widal positive. Blood culture positive. On the day after admission a lumbar puncture was performed, 25 c.c. of fluid being obtained. Smear showed the presence of lymphocytes and endothelial cells. Motile bacteria were present in the hanging drop. Culture showed the presence of typhoid bacillus. Patient recovered.

This is a satisfactory case.

Case IV.—Nieter 1908, *Münchener med. Wochenschrift*, V. 55, p. 1009. Patient aged 30, entered the hospital November 22 on the second day of illness. Onset with headache and chilliness. On admission temperature was 39° C. Pulse was small and frequent. There was stiffness of all the extremities. The spleen was not palpable. No roseola were present. November 27 patient died, meningitis having been suspected. The typhoid bacillus was obtained from a puncture of the spleen. A lumbar puncture was performed post mortem and bloody fluid was obtained. The smear showed the presence of Gram-negative bacilli. Culture showed the presence of typhoid bacilli. No autopsy was performed.

Although blood was present in the cerebrospinal fluid, the fact that bacilli were present in the smear probably excludes contamination.

Case V.—Claret et Lyon-Caen: 1909, *Bull. et Mem. Soc. Med. d. Hôp. de Paris*, 3 s, V. 26, p. 217. Female, aged 23, entered the hospital April 20, on the sixth day of illness. Onset with headache, fever and lassitude. April 20-April 30, roseola appeared and Widal was positive. May 1, severe headache, photophobia and ptosis. May 3, rigidity of the neck, marked Kernig, pupils unequal. Lumbar puncture was performed, 15 c.c. of clear fluid being obtained. Smear did not show the presence of any bacilli. Cytology, polynuclears 60 per cent., mononuclears 25 per cent., red blood cells 15 per cent. Patient improved somewhat after tapping. May 4 another lumbar puncture was performed. Typhoid bacillus was obtained from culture of the spinal fluid. May 6, intestinal hemorrhage. May 8, delirium and incontinence of urine. Lumbar puncture was performed, 10 c.c. of clear fluid being obtained. Smear showed the presence of lymphocytes and red blood cells. No organisms present in the smear or culture. May 8 to 17, amelioration of the symptoms. May 17, lumbar puncture was performed. Smear showed the presence of lymphocytes. Culture sterile.

The high polynuclear count in the spinal fluid makes the correct diagnosis probable.

Under the third group the so-called "suppurative meningitis" there have been six cases:

Case I.—Staubeii: *Deutsches Arch. f. klin. Med.*, Leipzig, 1904-1905, V. 82, page 90. Male, aged 22, entered hospital June 28, on third day of illness. Onset with chills, violent headache and sore throat. On admision there was slight rigidity of neck. June 28 to July 2, headache severe. July 2, a lumbar puncture was performed, 10-15 c.c. of clear fluid being obtained. Headache somewhat relieved after tapping. July 3, roseola present. July 5, Widal positive. July 9, headache returned. July 12, slight Kernig present. July 14, apathy and rigidity of neck marked. July 15, twitchings of fingers, strabismus, delirium, and coma. July 16 another lumbar puncture performed, 50 c.c. of purulent fluid being obtained. Smear showed numerous bacilli and polynuclear leucocytes exclusively. *Bacillus typhosus* was obtained from culture. July 17, died. At autopsy, slight healed lesions of typhoid fever; suppurative cerebrospinal meningitis; abscess of the right frontal lobe. Microscopic examination: marked round celled infiltration, especially about the vessels of the pia and extending into the brain substance. Numerous bacilli present. The same lesions were found in the spinal cord.

This is a positive case.

Case II.—Delille: 1905, *Pediatric prat.*, Lille, V. 3, p. 89. Female, aged 9, entered hospital November 13, 1904, on the sixth day of illness. Onset with headache, anorexia, malaise, constipation, and fever. November 14 roseola present, Widal positive. November 22, spleen palpable, headaches persistent. December 6, Kernig marked. December 11, reflexes increased; a lumbar puncture was performed, 6 c.c. of slightly cloudy fluid being obtained. Smear showed predominance of lymphocytes and very few polynuclear leucocytes. Culture showed the presence of *Bacillus typhosus*. December 13, intestinal hemorrhage. December 14, coma, convulsions. December 15, died in coma. At autopsy, cicatrization of ulcers of Peyer's patches; ulcer of the cecum; suppurative cerebrospinal meningitis. The details of the cultural characteristics of the organism and agglutination test are not given.

In all probability a positive case.

Case III.—Henry and Rosenberger: 1908, *Am. J. M. Sc.*, Phila., n. s., 135, p. 240. Male, aged 34, became ill six days before his admission to hospital. Onset with headache, dizziness, vomiting, delirium, and fever. On admission the patient in coma, ptosis of both lids, pupils are small, equal, and do not react to light; neck rigid; Kernig present. A lumbar puncture was performed on the following day (April 4), 25 c.c. of a turbid fluid being obtained. April 5, knee jerks absent, lumbar puncture again performed, 30 c.c. of a turbid fluid being obtained. Smear showed the presence of bacilli, polynuclears 76 per cent., lymphocytes 2 per cent., hyalin cells 2 per cent. Culture, typhoid bacillus. Patient died April 6. At autopsy catarrhal enteritis, with slight enlargement of Peyer's patches and mesenteric lymphnodes, suppurative cerebrospinal meningitis. Microscopic examination, infiltration of the membranes of the brain and cord, with lymphocytes and polynuclear leucocytes. Bacilli present. Typhoid bacillus was obtained from the pus at autopsy in smear and culture.

This is a positive case.

Case IV.—Southard and Richards: 1908, *J. Med. Research*, Boston, V. 19, p. 513. Male, aged 22, had tabes and general paresis for two years. One week before death temperature rose 103°, and died from what seemed to be a bronchopneumonia. He was unconscious for two days before death. At autopsy hypostatic pneumonia, enlargement of the mesenteric lymphnodes, acute cerebrospinal meningitis, typhoid bacilli were obtained from culture of the lymphnodes and from the pus of the meninges. Miscroscopic examination: there was an infiltration of the piaarachnoid of the brain and cord with polynuclear leucocytes and mononuclear cells, the former, however, predominating. In addition the lesions of tabes and paresis were present.

This is a positive case.

Case V.—Lavenson: 1908-09, *Univ. of Penn. M. Bull.*, Phila., V. 21, p. 55. Female, aged 26, entered the hospital April 22, 1906, on the fifth day of illness. Onset with headache, vomiting, photophobia and fever. April 25, delirious. April 26, Widal positive. On April 27 a lumbar puncture was performed. April 30, neck rigid. May 3, hematuria. May 4, edema of the lungs and died. Culture, *Bacillus typhosus*. Autopy performed 24 hours after death, body being embalmed: Purulent meningitis, no intestinal lesions, no enlargement of the spleen. Smear of the pus showed presence of Gram-positive and Gram-negative bacilli.

This is a positive case, the Gram-positive bacilli probably being post morten contamination.

Case VI.—Symmers and Wilson: 1909, *J. Bact. and Path.*, Cambridge, V. 13, p. 251. Also reported by Milligan: *British Medical Journal*, Lond., 1908, V. 1, p. 1295. Male, aged 37, entered the hospital August 23, on the eleventh day of illness. Onset with headache, vomiting and delirium. On admission, diplopia, internal strabismus of the right eye. Neck rigid, Kernig present. Spleen felt with difficulty. August 25, twitchings. Pupils sluggish and contracted. Incontinence. Widal positive. August 26, died. No autopsy was performed. A lumbar puncture performed one hour after death, turbid fibrinopurulent fluid being obtained. Cellular elements, polynuclear leucocytes 40 per cent., small lymphocytes, 22 per cent., large lymphocytes 32 per cent., transitional cells 6 per cent. Culture, *Bacillus typhosus*.

This is a positive case.

Reference has also been found to Moda: *Chirigai Iji Shimpo*, Tokio, 1906, V. 27, p. 577. (Not accessible.)

I desire to thank Dr. Cleaveland, in whose service this case occurred, for permission to report this case, and also to thank Dr. Norris and Dr. Pappenheimer for their cooperation.

261 Seventh Street.

THE SAW AND CRUSHING INSTRUMENTS IN SURGERY OF THE NASAL SEPTUM.

By BRYAN DeF. SHEEDY, M.D.,

NEW YORK.

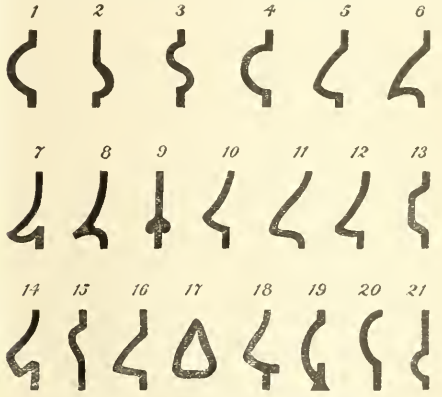
ADJUNCT PROFESSOR OF RHINOLOGY AND LARYNGOLOGY, FORDHAM UNIVERSITY MEDICAL COLLEGE; INSTRUCTOR IN DISEASES OF THE UPPER RESPIRATORY TRACT, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; MEMBER OF THE LOCAL COUNTY AND STATE MEDICAL SOCIETIES; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION.

Men following nose and throat work as a specialty have seen many and marked changes recommended by rhinologists during the past few years in the special procedures suggested for the correction of the many deformities of the nasal septum with

which we daily come in contact. The number of inquiries made by under- and post-graduate students during the past few years leads me to conclude that all rhinologists are not yet in accord with the idea that the saw and crushing instruments are useless and unnecessary for the correction of the many obstructive difficulties due to deformities of the nasal septum in which we are called upon to operate. From an investigation made by me I am in a position to state that there are very few textbooks in print to-day, whether issued this year or during the past ten years, that do not give up many pages of their space to the describing of operations that are no longer useful or to be recommended, and, in fact, have long since been found unsatisfactory to both patient and surgeon. In conversation, recently, with a large number of prominent rhinologists from all parts of this country and Canada, I was pleased to learn that the saw and other crushing instruments, formerly recommended in our work on the septum, have been laid aside and nearly all the procedures and operations heretofore used have given way to the submucous resection operation, as recommended in Europe by Killian, of Freiburg, and in this country by Freer, of Chicago. You will not have examined many nostrils, particularly those patients with the cramped adenoid noses, without discovering that practically all have deviated septa. When you use the expression "deviated septum," however, you do not fully describe the deformity which is usually found, for in almost every case that I have seen there has been a deposit of bone or cartilage cells on the septum resulting in ridges or spurs, in connection with the deformity.

Statistics say that about 95 per cent. of all septums are abnormally deviated, the deviation existing in either the cartilaginous or the bony portion. In probably 60 per cent. of these cases, in addition to the deviation, you will find well-marked crests or ridges, extending backward and upward, usually beginning at a point where the anterior tip of the vomer joins the crest of the superior maxillary. This ridge or crest extends along the line of union between the vomer below and the cartilaginous and ethmoidal plate above. Sometimes this crest or ridge is cartilaginous, sometimes bony and sometimes bony and cartilaginous. The location of this ridge or crest, extending into the middle meatus, blocks and obstructs it according to its shape. Occasionally you see these spurs or sharp projections extending across the whole width of the middle meatus, penetrating portions of the middle turbinate or the lateral nasal walls. In pointing out the varieties of deviation which I have observed, I desire that you should interpret them with deposits of cartilage or bone cells here or there on the deviation, forming the ridges, spurs, spines, etc., to which I have above referred. In addition to attracting your attention to the deformities shown, I desire to refresh the reader's mind on the normal structures of the septum.

The upper breathway is divided or separated by the septum into two passageways, known as the nasal fossae. The septum articulates above and behind with the nasal bones, the frontal bone, the ethmoid and the sphenoid. Below the nasal bones, in front, it is intimately connected with the under surface of the triangular cartilages and soft structures that go to make up the prominence of the nose. On its inferior border it articulates with the spinous process of the superior maxillary bone. In front and extending backward for the length of the quadrangular cartilage, we have interposed wedge-shape pieces of cartilage, between the quadrangular cartilage and the crest, designated the vomerine cartilages. These vomerine cartilages frequently extend beyond the perpendicular line of the septum, causing what is known as the vomerine ridge or spur. You will recognize the fact that this is the vomerine cartilage, ridge or spur through the fact that this ridge or spur never extends further back than the posterior edge of the quadrilateral cartilage. Behind these vomerine cartilages the articulation is between the plate of the ethmoid and the vomer and the superior maxillary bone. We seldom have deviations or projections on the line of the articulation between the vomer and the crest of the superior maxillary; the ridge, spur or deviation usually appearing higher up on a line between the vomer and the perpendicular plate of the ethmoid. When we



Various types of deviation of the nasal septum.

study the functions of these two irregular passageways, divided by the nasal septum with the two well-marked, turbinate shelves on the outer wall of each, we find that the whole surface is covered by a special form of mucous membrane; that in the upper part and limited to a very small area are the special olfactory sense bulbs. A study of the anatomy and functions of the upper breathway must lead anyone to conclude that an error was made in considering the nose the special organ of the sense of smell. Not more than 1/100 part of this mucous surface is devoted to the special sense, while 99/100 parts are devoted to other and special functions. The three important functions of the nose, that is, the warming, moistening and filtering of the inspired air, should at all times be borne in mind; for upon the presence or absence of the performing of these functions properly depends the necessity for operative interference.

The accompanying drawings will show the forms of deviation of the septum to which I have before referred. In some of these deviations, particularly in the S-shaped variety, the nostrils will be blocked both anteriorly and posteriorly. When we come to study the symptoms manifested by these deformities we must consider that they will depend upon the age of the patient and the general physical conditions, as well as upon the climatic conditions in which the patient lives. The malformations outlined divert the air current from its normal course and are directly responsible for the inflammation and congestion so often seen in other parts of the upper

breathway which help to block the passageway to normal respiration. It has been said "That a man who breathes through a perfectly healthy nose is entirely indifferent to the severest extremes of heat, cold, dryness and humidity. That the nose is capable of preparing a climate, the atmosphere of which can come in contact with the sensitive lung tissues without creating irritation." The mucous membrane covering the whole of the upper breathway is filled with mucus and serum secreting glands capable of pouring out hot water so rapidly that by the time the driest air reaches the larynx it is saturated with moisture and the temperature raised to that of the blood. The circulation of this mucous membrane, particularly that of the inferior turbinates, is most active and performs a very important part in the warming and moistening of the inspired air. The great necessity, therefore, exists for us to always give the greatest amount of consideration and deliberation to these structures before removing a part or the whole of them.

If the passageway is crowded and there is a lack of room, always attack the septum rather than the structures which contribute so much to the important functions above enumerated. The inferior turbinates act, not only as irrigators and radiators, but also as sentinels. The duties performed by these sentinels are very apparent when a blast of cold air is drawn into the nostrils. At once the structure swells up, becomes erect and by its presence blocks the passageway and interferes with a large current of cold air passing into the lungs, without having the proper nasal functions performed upon it, and possibly causing irritation with resulting bronchitis and lung difficulties. We have all experienced the feeling of stuffiness and suffocation that comes over us in passing from a warm room into a cold one or vice versa. This stuffiness or suffocation is brought about by the overactivity of the sentinel-like functions just enumerated. The presence of new cell formation in the turbinates modifies, to a very great extent, the sentinel action of the latter; so that in considering the proper treatment of a diseased turbinate this fact should always be taken into consideration. Other factors also contribute to the irregular workings of the turbinate, and I would especially mention overeating, overdrinking and the overstimulation that comes from the inhaling of irritating tobacco smoke, snuff and large quantities of dust. Especially is this to be taken into account nowadays when the streets are so very dusty on account of excessive motor car driving; and here in New York we are already face to face with the condition existing on our principal thoroughfare, where our richest and most well-to-do patients are compelled to inhale an atmosphere loaded down with gasoline oil carbon particles. Constipation, gout, and rheumatic conditions also play an important part in the functions and in the producing of symptoms in connection with the normal breathway.

It is, therefore, almost unnecessary for me to emphasize the point that if this mucous membrane, which has so much to do with the general well-being of our patient, is to perform its functions normally and properly it must not be hampered, restricted or interfered with, through destroying its ciliated epithelia, by the performance of lacerating and crushing operations. The important point, therefore, is that we should always, under all circumstances, preserve the ciliated epithelia of the nose as far as it is in our power to do so. We are all familiar with the large number of crusty accumulations that patients complain so much of and that usually follow the use of the saw. So far as I know, there is really no good excuse, to-day, why the saw should be used in the nose; for I know of no deviation or deformity of the nasal septum which cannot be better relieved through the submucous resection operation than by any of the cutting or crushing operations that have been so extensively used in the past and that are still so extensively described in many of the text-books. It is quite impossible to use the saw without lacerating a large amount of mucous membrane with the resulting scar tissue on which cilia will not develop, but on which forever after we have annoying crust formations and accumulations.

In the submucous resection operations, as advised by Killian, of Freiburg, and Otto Freer, of Chicago, with the many modifications that have been recommended and found serviceable through experience, we have procedures that will prevent our patients from suffering many of the difficulties and annoyances they have experienced in the past, following the use of the saw. I refer particularly to the annoying crust formations that most patients complain of. In regard to the symptoms from which patients suffering from the deformities outlined complain, it has been my experience that the location of the deviation and the nervous makeup of the patient have more to do in creating them than any other two conditions that we find. Nearly all patients, however, suffer from a sense of stuffiness in the nose and pain over the frontal region or bridge of the nose, especially if the deviation has been sufficiently marked to interfere with the discharge of the normal secretions from the ethmoidal and frontal sinuses. Dizziness is a frequent symptom if the flow of the secretion from the ethmoidal cells is interfered with; while asthmatic attacks are frequent when the deviation presses on the middle turbinate or when the middle turbinate presses upon the septum, or when the ethmoidal cells are distended by hyperplastic material. Nasal discharge, both anterior and posterior, either of the watery or thick mucus, is a frequent symptom. This so-called nasal catarrh is usually diagnosed and complained of by all of these patients. The symptoms of obstruction, where the nostrils are either completely blocked or only partially so are manifest through the mouth breathing of the patients. All the symptoms vary as to the patient and also as to whether or not both nostrils are completely or partially blocked all of the time or only part of the time. If the obstruction be complete and brought about through bony conditions then the symptoms of obstruction are permanent and the patients are constant mouth breathers. But if the obstruction in one nostril is due to the deviated septum and the obstruction in the other to the intumescent condition of the inferior turbinate resulting from overwork, the symptoms are not so pronounced, because there are times when the patient can breathe through one nostril. The disturbances of phonation, from which all these patients suffering from nasal obstruction complain, should not be overlooked; especially in those who strive for musical notes in both speaking and singing. Nasal obstruction is quite a serious matter for anyone fitting himself for an operatic career.

The dry pharyngitis and laryngitis in adults, the dry tongue for which these patients complain on arising in the morning and the loss of recuperation from a good night's sleep, are all due to the mouth breathing in these cases. The anemia so well-marked in mouth breathing patients, is, I believe,

due directly to the lack of absorption of oxygen; for as you know, atmospheric air which is not properly prepared for absorption into the lungs by passing through the nasal laboratory will not give up its oxygen for absorption. Such air, instead of giving up its oxygen and being a benefit to the mucous membrane of the lungs, acts as an irritant and is the direct cause of many coughs and attacks of bronchitis from which these mouth breathing patients suffer.

Mouth breathing due to deformities of the septum is seen but seldom in children under eight or nine years of age, excepting where traumatism has been suffered. Obstructions of the breath way before that period are usually in the nasopharynx. It is very important, however, for all practitioners who operate for the removal of adenoids and tonsils, to examine the nasal breath way carefully for obstructions created by the turbinate bodies, before giving an opinion that an operation for the removal of adenoids will relieve the patient from mouth breathing and from injurious symptoms associated with nasal and postnasal obstructions. Many unrelieved cases are due to obstruction in the nose, due to enlarged turbinates. Practically all the difficulties of hearing, not traceable to diseases of childhood, rheumatic and sclerotic conditions, can be traced to nasal obstructions, septal deformities and chronic catarrhal conditions due to these deformities and obstructions. Many of the neurotic conditions of childhood can be directly traced to postnasal obstructions; while in older patients, hay fever, epilepsy, chorea and many other nervous disorders have been permanently cured by the correction of the deformities referred to. It is only necessary for you to read the papers and discussions in the Section on Rhinology and Laryngology at the last Convention of the American Medical Association to be convinced that nearly all the leading rhinologists of this country, to-day, are using the submucous resection operation for the cure of the conditions herein outlined, to the almost complete exclusion of the numerous operations heretofore recommended in which the saw or crushing instruments were used. The results of the submucous resection operation are so uniformly satisfactory to both patient and operator in all the conditions herein outlined that there is hardly any excuse why other operations, not so satisfactory, should be taught in the schools or described at length in modern text-books. The only exception to this, that I can think of, is in descriptions which are given as a mere matter of history.

The danger of the nose sinking or becoming depressed, as I have before pointed out, does not exist at the present time if the operation is performed as now recommended.

Formerly, in the crushing and cutting operations, patients were compelled to be away from business from six weeks to two months and during this protracted period were compelled to wear an annoying, painful and depressing hard rubber or metal splint; while with the submucous resection operation, the nostrils are lightly tamponed with a soft material for not more than twenty-four hours and the patient is able to return to business on the third or fourth day following the operation.

Dr. Otto Freer of Chicago, to whom I sent a copy of this paper in manuscript, has written me as follows: "I have looked over the advance sheets of your article and am pleased to be placed on record as being in accord with you and all progressive rhinologists who take their work seriously and prefer well planned and exact intranasal surgery, which gives the best results with the least injury, to the crude hit-or-miss operations which are employed even in this progressive age by some operators. I am wholly in accord with you in discarding the saw and crushing instruments in the correction of deflections of the nasal septum and in the removal of bony and cartilaginous prominences. It is unfortunately true that both the saw and the fracturing methods are still used. Many operators employ them because they have not yet mastered the difficulties of the submucous resection. Others have reverted to them after a trial of the up-to-date methods of operations, following preconceptions of its demands rather than anatomical indications, and represent it as so simple a procedure that it may be performed in a few minutes' time. This misconception has led many to abandon the submucous resection because of unsatisfactory results, traumatism, perforations and depressed noses. The author of the most popular of these methods has recently found it necessary to restrict the submucous resection to "selected cases," reserving the general run of cases for the uncertain fracturing operations of an older era. This is a retrogression not even thought of by the surgeons who have mastered submucous resection and in whose hands it has become a procedure of such mathematical precision that their reports show that they employ it with increasing satisfaction in all deformities of the septum, and with the knowledge that it gives the desired breathing space and preserves the normal physiology of the nose intact, while hundreds of dissatisfied patients are constantly seeking the newer operation where the septum has been damaged by previous operative attempts and though the difficulties are greatly increased, even these patients are permanently relieved.

"Permit me to state that my procedure, though you mention it in the same breath with Prof. Killian's of Freiburg, has been developed independently of his operation since 1901 and was described in two articles by me before Killian's first detailed publication. My methods share with that of Killian merely in the indication to remove the deflected bone and cartilage with the preservation of the mucous membrane. The steps of the operation are, however, entirely different. The Killian method depends upon the elevation of the coverings of the deviation with blunt instruments through a cut on the front of the septum, while in my operation the whole proceeding is done in an open operative field where every step can be carried out with surgical precision. The steps of the operation, as now performed, were described in the *Illinois Medical Journal* for May, 1910, and in that article I have gone into details as to the extent the flap should be left so that after the removal of the deflection there will be exact adaptation of the mucosa. So far as I am able to judge there is no need of depressed noses, perforations or other accidents and I have never known a saddle nose to follow the submucous resection with my open flap method.

"Your recommending the freeing of the nasal passages in septal deviation by properly performed submucous resection, instead of partly clearing them by cutting down the turbinated body, is timely, as I have seen many patients who have been operated upon in this manner without relief. The resection of the deflection affords freedom of respiration from the nasal floor to the nasal vault without interfering in any way with the physiological functions

of the turbinated bodies. I am pleased to commend the advice given to resect spurs and ledges of bone and cartilage to the mucosa of the opposite nostril, as these prominences are merely the projected portions of deviations and are to be removed with them to obtain the best possible results."

In conclusion, therefore, I will say that, judging from our experience and from the favorable reports made to us by our patients, the saw should be discarded as well as all crushing instruments heretofore advised, and which are still recommended in many of the text-books; and that all the deviations, spurs, outgrowths and exostoses of the cartilaginous and bony septum should be corrected by the submucous resection operation.

164 West Seventy-third Street.

GONOCOCCUS URETHRITIS IN MALE CHILDREN.*

By ABRAHAM LEO WOLBARST, M.D.,

NEW YORK.

CONSULTING GENITOURINARY SURGEON, CENTRAL ISLIP STATE HOSPITAL; ATTENDING GENITOURINARY SURGEON, BETH ISRAEL HOSPITAL AND WEST SIDE GERMAN DISPENSARIES; PROFESSOR OF VENEREAL DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC., ETC.

This paper is intended as a simple contribution to a subject that has not received the attention that it deserves. A survey of the more recent literature on the subject of gonorrheal infection in children reveals the striking fact that nearly all writers on this subject, while speaking of gonorrhea in children, confine their remarks to the consideration of the disease in young girls only, without paying any attention whatever to the disease as it occurs in male children. Consequently, though much has been written on the subject of gonorrhea in young girls, very little can be found relative to the occurrence of this disease in young boys.

This is probably due to the fact that gonococcus infection of the urogenital tract is much less frequent in male children than in female children. The anatomic arrangement of the female genitals, especially in childhood, presents a soil that is highly favorable to infection from without, and it would seem that this is sufficient, if a reason were desired, to account for the greater frequency of the infection in girls than in boys. Another plausible reason for the great relative difference in the occurrence of this infection in the two sexes is perhaps found in the fact that the tendency for adult males to tamper with female children is greater than for adult women to indulge in sex relations with male children; hence the greater risk of infection.

Gonorrhea in male children is not a rare condition. It is seen most frequently among the poor of large cities, where the crowding and congestion offer a fine opportunity for the maintenance of the disease as an endemic affection. It is thus apparent that the prevalence of gonorrhea in male children is not to be considered only from the purely surgical standpoint, but also from a sociologic point of view. It is quite customary for these young children to sleep in the same room with their parents or with adult boarders; there is no semblance of privacy whatever in many of these homes, and as a result the children are at a very early age made aware of sex conditions and sex differences. It is, therefore, not unusual for these young boys to indulge in coitus with young girls of their own age, or with adult women, and the remarkable feature is that the number of cases of gonorrheal infection is so small, rather than so large, in view of the extensive intermingling of the young of both sexes and the precocity and extent of their sexual knowledge. Our esteemed president, Eugene Fuller, has mentioned this precocious indulgence in coitus by young boys as an important factor in the development of chronic seminal vesiculitis and sexual neurasthenia later in life.[1]

In 1901 I had the privilege of reporting 22 cases of gonorrhea in boys, ranging in age from 18 months to 12 years,[2] Since that time I have had the further opportunity of studying 15 additional cases, all of them seen in dispensary practice, the youngest being a child 16 months old, and the oldest 14 years old. In all of these cases, without exception, the diagnosis of specific infection was made certain by the microscopic examination of the secretions by the Gram stain.

This total of 37 cases has presented several points of unusual interest, which justify this paper:

The age of the patients was as follows: Sixteen months old, 1 patient; 18 months old, 1 patient; 2 years old, 3 patients; 4 years old, 7 patients; 6 years old, 5 patients; 7 years old, 3 patients; 9 years old, 2 patients; 10 years old, 2 patients; 12 years old, 3 patients; 13 years old, 4 patients; 14 years old, 6 patients. The cases thus divide themselves according to age, namely: 2 years or under, 5 cases (14 per cent.); from 4 to 10 years, 19 cases (51 per cent.); from 12 to 14 years, 13 cases (35 per cent). It must not be inferred from these figures that male infants under two years of age enjoy any special immunity from gonococcus infection; the small proportion of infants in this series of cases is explained by the fact that such cases are most commonly brought to the pediatrist or the general practitioner, rather than to the genitourinary surgeon, both in private and institutional practice.

The largest percentage of infections is seen to be found in boys from four to ten years of age—the age at which sexual instinct and curiosity develop hand in hand with the general growth and intelligence of the child. It is in children of this intermediate age that adult sexual perverts are especially interested; they are old enough to satisfy the unnatural cravings of these perverted minds, and young enough to not understand the seriousness of the act in which they are induced or forced to take part. I believe that it is these children that bear the brunt of that superstition of world-wide extent to the effect that contact with a child of the opposite sex will rid an adult of venereal disease. In better social circles, where nurse maids often sleep with their charges and at times carry on sex relations with them, the victims are usually of this most susceptible age. In this class of cases is the one reported by Pollack[3] of a six-year-old boy viciously infected by his nurse girl, who was sentenced to seven years in prison for the act.

The next largest percentage is found in full-grown boys, from twelve to fourteen years of age. These boys are at the threshold of puberty, and most if not all of them are thoroughly alive to all the possibilities of the sexual function and the means for its gratification.

Infection may be direct or indirect. While indirect infection is quite common in female children, it is but rarely so in male children, for reasons already mentioned. There is, however, one form of indirect infection in boys that is worthy of our

*Read before the ninth annual meeting of the American Urological Association, June 6, 1910, at St. Louis, Mo.

serious attention—namely, infection through the urethral catheter in hospitals. This shall be considered later. In most cases, however, infection is direct, either through coitus or through the practice of sexual perversions. The sex instinct is at the bottom of most of these cases. Zobel[4] reported three cases of rectal gonorrhea in young men, 10, 18, and 20 years of age, and in view of the fact that many young boys in crowded districts indulge in the practice of sodomy, it is quite probable that this is a somewhat frequent mode of infection. As an unusual instance of indirect infection, Fraser-Harris has reported[5] the case of a boy 14 years old, who contracted a severe gonorrheal urethritis by wearing a pair of contaminated drawers. This is, however, a very unusual occurrence in boys.

Careful inquiry was made in every case that came under observation as to the manner in which the child was infected, this being considered a most essential part of this study. In seven cases the most thorough inquiries were futile. In the remaining 30 cases, however, interesting information was revealed.

In nine cases (24 per cent.) the infection was presumably derived accidentally from some member of the household. In these cases investigation revealed the information that the child slept in the same bed or used the same toilet utensils as some other member of the family, and there was sufficient corroborative evidence in most of the cases to make it reasonably certain that this member of the family was suffering from gonorrhea. For instance, two children slept with their fathers. When the latter were confronted, both admitted having gonorrheal urethritis at the time. Five children slept with the mothers, all of whom were at the time under treatment for various gynecologic diseases. One child slept with his elder sister, and another slept with a female boarder; in both of these cases the suspicion was quite justified.

Direct infection through coitus was admitted by twelve boys. They admitted having had sexual relations with young girls or women, and the periods of incubation seemed to indicate that these females were the actual source of the infection. As indicative of the existence of a precocious sexual instinct in these young children, which, by the way, some writers deny, their ages are of interest: Four years old, 1 patient; 7 years old, 1 patient; 9 years old, 1 patient; 10 years old, 2 patients; 12 years old, 1 patient; 13 years old, 2 patients; 14 years old, 4 patients.

It is of further interest to observe that the younger boys declared that older girls or women had made the first advances to them, and that they consented against their will, sometimes under duress and threats of punishment. Most of the older boys, however, *i. e.*, those over nine years old, frankly admitted that they had had coitus with girls of their own age or younger, or with adult women, at first as a matter of curiosity when the opportunity presented itself, and later for the pleasure they found in the act. In three cases the infection followed after but a single coitus, according to their statements. One boy of twelve solemnly asserted that he had never indulged with any girl other than his own sister, aged eight. Examination of this girl confirmed the suspicion that she was the source of the infection. It is of further interest to note that most of these boys had good records at school, and were not considered bad boys either by their parents or by their teachers.

I have already referred to the existence of the superstition relative to the cure of gonorrhea through contact with a virgin of the opposite sex. There is no way of proving that any of these cases of infection were the sequelæ of this superstition, but inasmuch as they all came from the poor, tenement district, where the women who harbor this superstition also live, it is quite plausible that some of these patients, at least, became its sacrifice. The majority, I believe, were infected as the result of gratification of their own precocious sexual desires, which are highly developed among the children of the poorer districts.

The remaining nine boys were infected while they were in hospitals suffering from various diseases of childhood. I have become especially interested in this mode of infection because of the utter lack of excuse attendant upon it. There seems to be no reason on earth why a child should enter a hospital suffering from diphtheria or pneumonia, and survive the disease, only to come out with a well-developed case of gonorrhea of the genital tract. While we may believe with Holt,[6] that it is impossible to prevent these outbreaks among girls, it seems to me that this ought to be a very rare accident where boys are concerned.

Once the child is infected, the period of incubation and the general course of the disease do not vary from that of the adult. As a rule the pain on micturition appears a day or two before the discharge. Sometimes the pain is so great that the child is afraid to urinate, and complete retention or dribbling may set in. The pain is at times out of all proportion to the clinical symptoms. This hyperesthesia, as I have already shown,[2] is usually found coincident with a contracted meatus or a tight prepuce, which act as a dam to the secretions, and by preventing proper drainage of the canal, cause more or less complete retention and an increase of the inflammation. On the other hand, some children suffer very little pain, and would not be brought for treatment, except for the redness at the meatus and the discharge.

Complications similar to those found in the adult may also occur in male children. In this series of cases there were no complications worthy of note, but other observers have reported them. Holt[6] observed 26 cases of gonococcus arthritis in children; of these nineteen were male, and seven female. The symptoms were a rapidly developing articular swelling, redness, tenderness, and when suppuration was imminent, fluctuation was present. The temperature frequently reached 103, and sometimes 104 and 105, and lasted from one to eight weeks. Death followed in a number of these cases, the patients succumbing to marasmus. In general the disease runs the same course, and subjects the patient to the same dangers and complications as are seen in the adult.

The prognosis is rather better than in the adult. In young boys I have been unable to observe that innate tendency to chronicity that is characteristic of the adult infection, and strictures do not as a rule follow. Recovery is as a rule quite complete. Taylor[7], however, mentions two cases reported by Rona, in which stricture seems to have followed years after the attack. In one, a boy of 17, the stricture probably began in an infection at the age of 10; the second case was that of a medical student aged 21, who also was infected at the age of 10. Taylor adds that it is very probable that to virulent gonorrheal urethritis occurring in early life may

be attributed many of the cases of stricture in boys and young men in whom a history of recent gonorrhea cannot be obtained.

As to treatment, the primary requisite is cleanliness. If the child has been circumcised this problem will not be a difficult one, and many of the complications may thus be averted; when the prepuce is present, however, the greatest care should be taken to remove the intrapreputial secretions, and to provide the fullest measure of urethral drainage. Occasionally a dorsal incision will be imperative; likewise meatotomy is sometimes indicated. This can be done in the presence of a profuse discharge, without danger of infection.

For the urethritis itself the treatment is the same as in the adult, but the solutions should be proportionately weaker. I have found protargol 1-400 and argyrol 1-100 the most satisfactory agents in the local treatment. A small hand syringe is employed; about two drams are injected into the urethra slowly and carefully, twice daily, and retained for five to ten minutes. The more severe the inflammation, the weaker the solution and the smaller the quantity to be used. As a rule, the child soon becomes reconciled to the injections and accepts them in a philosophic spirit of non-resistance. Extensions into the posterior urethra and complications should be treated as in the adult. In my former paper[2] these matters were discussed at greater length.

Summary.

1. Gonococcus infection in male children is not a rare condition, though it is far less common than in female children.

2. Infection is usually the result of precocious sexual activity, or accidental infection in the home; sexual perverts undoubtedly infect a goodly number of children.

3. In hospitals a fairly large number of infections take place, presumably through infected catheters, etc.

4. These young patients are liable to all of the extensions and complications that occur in the adult.

5. It is possible that many cases of sterility, sexual neurasthenia, and urethral stricture are due to gonococccus infection in childhood.

6. The treatment is practically the same as in the adult.

Operative Treatment of Tuberculous Meningitis.—A. J. Cleveland describes the results in four cases of tuberculous meningitis in which trephining was performed for drainage of the base of the brain and for tapping of the lateral ventricles. The operative interference was useless, from which it is concluded that the increased intracranial pressure is not the immediate cause of death, which must be ascribed to the effect of the inflammatory process on the brain substance rather than on the meninges only.—*British Journal of Children's Diseases.*

THE BEDSIDE WIDAL TEST.

By George Gillman, A.B., Ph.G., Ph.C.
San Francisco, Cal.

This simple and efficient modification of the Widal Test is presented in view of fulfilling a long-felt want of the practitioner who is so often placed at a disadvantage and caused much inconvenience by the necessity of being dependent upon distant laboratories to make the test.

The new method requires no laboratory facilities or special technical skill and consumes such little time that it enables the practitioner to readily make the test at the patient's bedside and know the results within a few hours. The test, however, necessitates the use of a formalized culture of the typhoid bacillus which, although the practitioner is not expected to make, can be procured from almost any bacteriological laboratory and kept on hand ready for use at any time. It is prepared as follows: Each 100 c.c. of broth, contained in an Erelenmeyer flask, is inoculated with one (1) normal loopful of an eighteen (18) hour agar-slant culture of the typhoid bacillus. The inoculated broth is incubated at 37° C. for twenty-four (24) hours and then 1 per cent. formalin added and the flask kept at room temperature over night. On the following day tests for sterility are made and as soon as this is established the culture is filtered through ordinary filter-paper to remove any clumps which may be present. The culture should be put in small containers and stored in a cool dark place. This preparation, being a broth culture killed with formalin, there exists no dangers of accidental infection connected with its use, and it has proved itself to be as efficacious as a suspension of live bacilli. Furthermore, it presents an even suspension of the bacilli which will keep well for some length of time and always on hand ready for use. In the past few years this culture has gained much favor among laboratory workers, due to its many obvious advantages.

The test, the technique of which will be subsequently described, is based upon the principles of the original Widal reaction; and, though somewhat similar to the macroscopic agglutination tests now made in many laboratories in preference to the microscopical method, differs from that, in that the whole blood is used instead of the separated serum, and the technique so modified as to make the test available to every practitioner without the necessary special requisites required of the older methods.

Technique.—Into a very small test tube (5 mm. x 3 cm.) or homeopathic vial, place 48 drops of the formalized culture and to this add 2 drops of the patient's blood obtained in the usual manner from the lobe of the ear or tip of finger. The tube is next corked, shaken, and set aside. After having set from 3 to 5 hours, the tube is examined and the reaction noted, taking care not to disturb the fluid.

Interpreting the Reaction.—The formalized culture before use is always turbid, due to the suspension of bacilli. Now, if the added blood should give a positive reaction, the bacilli are agglutinated (clumped) and with the blood cells fall to the bottom of the tube, leaving the supernatant fluid clear. A *clear* supernatant fluid will therefore indicate a *positive* reaction. Should the supernatant fluid be *turbid* it will indicate a *negative* reaction.

When noting the reaction it is of material advantage to compare the supernatant fluid with some of the formalized culture contained in a similar tube as a control. In a positive reaction the fluid will be

decidedly clear as compared with the control, which is always turbid, while in a negative reaction the fluid will be as turbid as the control. During the early part of a positive reaction with a serum of low titre (agglutinating strength), the blood cells will first settle and then a flocculent precipitate (clumps) of bacilli will appear which later settle to the bottom, leaving the supernatant fluid clear.

Following out the technique as described, using forty-eight (48) drops of the culture and two (2) drops of blood, the size of the drops being as near alike as possible, an approximate dilution of one (1) in fifty (50) is made, considering two (2) drops of blood as one (1) of serum. Though, at best, only an approximate dilution is made, the reaction is sufficiently delicate and accurate to warrant it being of clinical value. Of course, the dilution may be varied to suit the worker by increasing or decreasing the quantity of either the culture or blood.

For agglutination tests other than typhoid, the same technique can be employed, replacing the typhoid culture by a formalized culture of the required microorganism.

It would be of great advantage to all concerned if some laboratory should furnish the practitioner with suitable vials containing the proper quantity of the formalized culture ready for use or the culture contained in a larger bottle accompanied by one or more suitable empty vials in which the test could be made any number of times, the vials being cleaned by simple washing before each new test.

EXOPHTHALMIC GOITER SIMULATING TYPHOID FEVER.

By LOUIS DLUGASCH, M.D.,

NEW YORK.

J. W.—Female, age 24. Was perfectly well up to two months ago. Habits as to sleeping and eating irregular. Previous history, negative; nothing of importance that has any bearing on the present condition was noted in the family history.

About six weeks ago the patient's attention was called to the fact that her eyes were protruding more than normal, but she paid no heed and went about her usual duties. Two weeks ago she began to complain of general malaise, headache, nausea, aching pain all over the body, and elevation of temperature. I was called in to see the patient and found that she was being treated for typhoid fever. I made a complete physical examination and found the following: General condition, poor; marked emaciation; slight dyspnea, no cyanosis or edema; ears, nose, and mastoids, negative. Eyes, eyeballs protruded (exopthalmus), Graef's sign present. Thyroid gland, enlarged slightly on right side, pulsation of gland. Throat, negative. Tongue, dry, coated with thick fur. Teeth and gums, sordes on teeth; gums normal. Skin, dry, warm, no eruption, no roseolar spots. Chest, symmetrical, expansion good. Lungs, negative. Heart, systolic murmur at apex; accentuation of second pulmonic; pulse rate ranges from 120 to 160. Abdomen, tympanitic, no masses, no rigidity, no tenderness. Liver, enlarged two fingers' breadth below the free margin. Spleen, very easily palpable. Reflexes, patellar reflex increased, fine tremor of hands.

Laboratory Findings.—Urine, negative, no Diazo-reaction. Blood, reds, 3,750,000; whites, 7,800; polynuclears, 72; lymphocytes, 28; Widal, twice negative.

When I first saw the patient she was running a temperature of 102° to 103.5° for about eleven days, both Widals were negative, and on the twelfth day temperature came down to 98.6°. The insidious onset with general malaise, headache, nausea, a tongue that looked like typhoid, sordes on tongue, enlarged spleen, would make one suspect typhoid fever. We must bear in mind the fact that in exophthalmic goiter we sometimes have rise of temperature with enlarged spleen, and it behooves us to make a careful physical examination. The drop in temperature on the eleventh day, of course, and both Widals negative, cleared up the diagnosis.

45 SECOND AVENUE.

Epidural Injections in the Treatment of Enuresis and Essential Incontinence of Urine.—Genaro Sisto records a case of essential incontinence of urine in a girl of twelve years which was entirely cured by epidural injection. Essential incontinence results from a lesion of the vesical center in some cases, as is seen in paraplegia and spina bifida. It may be spasmodic, the arc of disease including the peripheral conductor and the spinal cord, or of the nature of tic, when the cerebral cortex is implicated. We must carefully study heredity and local symptoms to determine which of these forms we have to deal with. Theoretically it is the traumatism to the canal that causes the cure. Practically we do not know the method of its action. The injections cause little pain and there is not any danger of injuring the cord, which separates into filaments that float loose in the cerebrospinal fluid. The injection is made at the lowest part of the sacrum in a triangular space between the sacral apophysis and two tubercles that are easily seen. The patient lies down for a half hour after the injection. This is an area in which there are a large number of veins, and circulation and absorption of drugs from this part is very rapid.—*Annales de Médecine et Chirurgie Infantiles.*

Serotherapy and Anaphylaxis in Cerebrospinal Meningitis.—V. Hutinel gives us records of four cases in which the serum treatment of cerebrospinal meningitis was interrupted by serious consequences of the nature of anaphylaxis. A final injection of serum, practised some days after the others, caused nervous phenomena that were serious and rapidly terminated in death. These accidents have been interpreted as the result of anaphylaxis. These results are more frequent and severe when the injections are made into the cerebrospinal cavities than when made into the peritoneum. The near proximity of the central nervous system seems to be of importance in these cases. A preventive treatment, called antanaphylaxis, has been attempted by various observers. The attempt to modify the toxins by physical and chemical means has failed. If too great heat is applied to the serum its anaphylactic properties are lost, but at the same time its curative properties are destroyed. If the serum be heated only to 56° its toxicity is modified and its therapeutic value does not suffer. All the sera prepared at the Pasteur Institute are now treated in this way. The injection into a sensibilitized person of serum of another animal also is of value in preventing anaphylaxis. Von Pirquet and Schick interpret these phenomena in this way: the injections cause a product of reaction to be formed, a sort of antibody; this substance acts on the antigen that is in the horse serum which has not as yet been completely eliminated. When a new injection is made the reaction occurs at once because there still remains antibodies in the organism. There are many obscure points about the subject of serum treatment. We should remember the possibility of the occurrence of serious symptoms in the use of sera as remedies, but we should not allow this to deter us in the saving of life by means of their use.—*La Presse Medicale.*

MILK CHARITIES IN THE UNITED STATES.

It would be useful and instructive in a high degree to learn with a certain amount of exactitude the influence that a milk supply exerts on the health of a population and especially the effect on the morbidity and mortality of infants. That milk has an important bearing on public health seems obvious, but it would be more satisfactory if we had exact statistics to drive home this point. In Great Britain, for instance, infant mortality under the age of five years is considerably less than in the United States and in Germany. Crowded urban conditions are more prevalent and the milk supply is generally not so well safeguarded in Great Britain as in the United States and yet infant mortality is lower. This appears to show that, while milk is an important factor in the rearing of children, there are other equally or more important factors. In *Public Health Reports,* September 30, the history, development, and statistics of milk charities of the United States are given in a paper by I. W. Kerr, Assistant Surgeon-General of the Public Health and Marine-Hospital Service, presented before the American Association of Medical Milk Commissions on June 6, 1910.

The Bureau of Public Health has cooperated with the above association, and at the suggestion of Henry L. Coit both bodies have concerned themselves with the collecting of statistics relating to infant mortality and the factors underlying its causation. Among other information which has been gathered is that the first milk depot founded in this country was established in 1889 and that similar institutions have been established in at least twenty cities. With the view of obtaining further information the Surgeon-General caused letters to be addressed to all the medical milk commissions, milk dispensaries, and milk committees, whose addresses were available, and to health officers in all towns of the United States of over 20,000 population. In this letter information was requested on twenty-four pertinent points, of which the last six were, perhaps, the most important. These six were: Is the milk heated. If heated, to what temperature and how long. Whether heat is applied winter and summer alike. What grade of milk is employed in the work. What was the mortality rate in the particular city for infants under one year of age. What was the mortality rate among the number of children who had been fed on dispensary milk one month or over during 1909.

The information received thus far indicates that there are twenty-eight cities in the United States in which are located infants' milk depots, and that about twice as much raw milk is distributed as pasteurized. The temperature to which the milk is heated varies from 147° F. to 170° F., and the time of heating is 20 minutes in almost all cases. In Chicago the milk commission causes the milk to be heated to 170° F. In Baltimore and in St. Louis the milk is given raw in winter and pasteurized in summer, and three institutions dispense both pasteurized and raw milk. All the institutions supply milk of the best quality. A comparison of the mortality rates of infants under one year of age fed on dispensary milk and of those fed in the ordinary way is impossible to arrive at. The Boston Milk and Baby Hygiene Association places the mortality rate of infants fed on dispensary milk at 2.5 per cent., while the mortality rate for infants under one year of age not so fed was 11.2 per cent. in that city. The Babies' Dispensary and Hospital, Cleveland, states that 1.49 per cent. of infants died under dispensary care and 7.3 per cent. under outside care. However, such data are more or less valueless, and it is only in Philadelphia, Boston, Baltimore, Cleveland, and Newark that any inferences whatever might be drawn from the comparative statistics. If information of definite value is to be derived from statistics the mortality rates should be based on the total number of births, in fact, statistics should be based on a regular system, so that the records kept and investigations made should be comparable.

There would, nevertheless, seem to be little doubt that the milk depots have exercised a considerable influence on infant mortality, for in cities in which they have been present for any length of time infant mortality has been reduced. As Kerr pointed out in his paper, morbidity statistics are of even greater importance to the sanitarian than mortality statistics. They not only indicate the severity of disease and its damage to society, but serve as a guide to prompt sanitary action. So far the collection of statistics relating to the prevention of infant morbidity has been fragmentary in the extreme. There are many features in regard to the milk question which need elucidation and therefore the action of the Association of American Medical Milk Commissions in cooperation with the Bureau of Public Health is to be highly commended.

THE DURATION OF PREGNANCY.

The explanation of the pregnant uterus quietly retaining a constantly growing fetus for a period of ten lunar months and then raising violent objection to its continued use as a domicile, an objection expressed in the form of contractions so vigorous and prolonged that they cease only with the expulsion of the contents or the death of the mother, is one of the most puzzling mysteries of physiology. That the period of continence is governed by definite laws is proven by the regularity with which, in

the great majority of cases, labor begins within a few days of the completion of the tenth lunar month, a fact so well recognized by both physician and laity that doctor and nurse are usually engaged months in advance.

When the date of the last menstruation before the onset of pregnancy is known the prophesy of the probable date of labor is comparatively easy and dependable. When, however, this date is not known, as a result of carelessness in recording it, in the instance of feeble-minded or insane women, or when a second pregnancy follows before the renewal of menstruation, the determination becomes far more difficult. For the solution of such problems Ellice McDonald, in an article in the September number of *The American Journal of the Medical Sciences*, offers a method of calculation which has at least simplicity in its favor. On the theory that the fundus uteri after the sixth month rises 3.5 cm. in the abdomen for each lunar month and at full term in just 35 cm. above the symphysis, the author lays down the following rule: "The duration of pregnancy in lunar months is equal to the height of the uterus in centimeters divided by 3.5." The measurement is taken with the patient lying on her back, the tape being allowed to follow the contour of the uterus from the symphysis to "the final dip" at the fundus.

The author, after six years of observation, says that "after six months this rule is extraordinarily exact." As the height of the fundus depends largely upon the size of the child, and as this may vary considerably in different infants in the same stage of pregnancy, such a rule as a means of forecasting the date of labor and of reducing the calculation to a matter of days would appear to lack exactitude. It is doubtless useful in an average normal case, but that it is of universal application and is more accurate than the old-fashioned calculation by weeks from the last menstruation requires confirmation before it is accepted.

The Prevalence and Geographical Distribution of Poliomyelitis in the United States.

Poliomyelitis has been present in epidemic form during the past two or three years in various parts of this country. Much has been learned concerning the disease in that period, but there is no doubt that as much, if not more, still remains for solution. From the public health standpoint it is manifestly desirable to ascertain as correctly as may be its prevalence and geographical distribution. With this end in view Surgeon-General Wyman of the Public Health and Marine-Hospital Service has caused to be written to the Secretaries of the State and territorial boards of health throughout the country letters of inquiry as to these points (*Public Health Reports*, September 30, 1910). The following information has been taken from the replies received: In Colorado one death from poliomyelitis occurred at Cripple Creek in July, 1909. In Connecticut the disease did not attract attention until June, 1910, when a slight outbreak occurred at Meriden with one death. Up to that time the disease had not been reportable to the State board of health. During July 18 cases with 2 deaths were reported. In the District of Columbia poliomyelitis is not required by law to be reported. However, physicians commenced to report cases during the latter part of July in this year. Up to July 31, 7 cases were reported. During the first 19 days of August 64 cases were reported. In Illinois in July, 1909, an epidemic of poliomyelitis broke out in Champaign County; thirty-two cases were reported with no deaths. In Kentucky, although poliomyelitis is prevalent, no statistics are available. In Kansas the disease appeared in epidemic form for the first time during the summer of 1909. In 1910, 57 cases and 15 deaths were reported in July and from August 1 to 20, 20 cases and 4 deaths. Poliomyelitis is not a notifiable disease in Maine, but several cases have occurred in three towns. The disease has appeared in Massachusetts during 1907, 1908, and 1909. In the latter year there were 923 cases. In Michigan there is no known epidemic. Minnesota seems to have been the hotbed of the disease. In 1909 238 deaths and about 400 cases were reported. It is estimated, however, that there were probably 1,000 cases or more. During the present year 36 deaths from the malady had been reported up to the end of June. Pennsylvania is another State in which poliomyelitis appears to have gained a foothold. In July of this year 152 cases were reported and from August 1 to 18 105 cases. Scattering cases have been found in 32 of the 67 counties. From Alabama, Georgia, Montana, Nevada, Ohio, Tennessee, Utah, Virginia, and West Virginia no information with regard to the disease is available, while the information from New York State was not available for insertion when the issue of *Public Health Reports* for September 30 was published. The remaining fifteen States had not been heard from. In order to cope successfully with poliomyelitis, which would seem to be increasing in this country, a knowledge of its prevalence and geographical distribution is almost essential. From the reports already received by the Bureau of Public Health it is plain that the disease is widely distributed. As has been pointed out, a somewhat remarkable feature of its distribution is that it does not seem to flourish in large cities. In Minnesota, where its ravages have been most extensive, the cases have occurred chiefly in the rural districts. The fact that the term commonly applied to the disease, infantile paralysis, is a misnomer becomes daily more evident, for a large number of adults have been attacked, especially in Canada.

The Registrar-General's Report for Ireland.

For the purpose of comparison some figures culled from the report of the Registrar-General for Ireland recently issued may be of interest to American readers. The population of Ireland is still decreasing through emigration, but at not so rapid a rate as in past years. There were 102,759 births registered during the year 1909, the number of deaths in the same period being 74,973. The death rate, 17.2 per 1,000, is 0.4 under that for the year 1908, and 0.6 under the average rate for the past ten years. Tuberculosis has always been a prevalent and deadly disease in Ireland, owing principally to overcrowding and generally unsanitary modes of living. Of late years, due in some degree to the efforts of Lady Aberdeen and the antituberculosis league, matters have improved. In 1909 tuberculosis stood highest in the mortality tables of Ireland with 10,504 deaths; heart disease came next with 9,052, and then in order old age, bronchitis, pneumonia, can-

cer, diseases of blood vessels, diseases of stomach and intestines, and kidney disease. The decrease in the number of deaths from tuberculous disease which was reported in the year 1908, namely 386, has been followed by a further decrease of 699 in the year 1909. Notwithstanding this reduction it appears that out of seven persons whose deaths were registered in Ireland in the year 1909, one was the victim of tuberculosis, or in other words, over 14 per cent. of the mortality in Ireland in the year 1909 was caused by tuberculous disease. The cancer mortality rate rose in Ireland in 1909, but this is said to be chiefly due to more careful registration and is more apparent than real. The proportion of deaths of infants under one year of age to every 1,000 births registered in Ireland during the year 1909 was 92. In this respect Ireland compares favorably with England, Scotland, and the United States, and the result is chiefly owing to the fact that the majority of the population of Ireland are country dwellers and that the women are so unsophisticated as to feed their infants at the breast. Ireland may be said, both materially and physically, to be in a more flourishing condition than has been the case for many years.

Sleeping Sickness and the Tsetse Fly.

It is stated that the results of the most recent investigations into the cause of sleeping sickness have tended to raise some doubt as to whether the tsetse-fly, *Glossina palpalis,* is really the sole carrier of the disease. The investigations which have led to the formation of these opinions have been carried out in certain districts of Rhodesia and in other parts of Africa in which cases of sleeping sickness have been known to exist, but in which not a single specimen of the fly in question has been discovered. Of course, it is impossible to exaggerate the importance of finding an explanation of this phenomenon and to determine the question as to whether any other insect is capable of transmitting the germs of the fatal disease. If it is the case that insects other than the tsetse fly can disseminate or act as the intermediary hosts of sleeping sickness it is essential to the future of Africa that all the means of transmission be discovered as soon as possible and that measures be promptly taken to stay the spread of the malady, otherwise the whole continent may be overwhelmed by its effects. Arrangements have been made with the British Royal Society and the Sleeping Sickness Bureau in London to send out at once a commission of experts to investigate the matter. The commission will be asked to furnish an early preliminary report on the results of their labors, including any recommendations which they may think it necessary to make in the direction of precautionary measures, bearing in mind the fact that the practice of isolation in case of infected natives of Uganda has proved entirely inadequate.

News of the Week.

Civil Service Examination.—On November 26, 1910, the New York State Civil Service Commission will hold examinations for the following positions: Assistant in experimental psychology, Psychiatric Institute, State Commission in Lunacy, salary, $1,500; men only. Assistant physician, Ray Brook Sanatorium, salary, $1,000 to $1,200; men only. Chief examiner, Board of Alienists, State Commission in Lunacy, salary, $5,000; men only. Application blanks must be filed on or before November 19, 1910. For detailed circular and blank, application should be made to State Civil Service Commission, Albany, New York.

Cholera in Naples.—Despite the optimistic tone of the official reports it appears to be the general belief that the situation in Naples as regards the cholera epidemic has not improved, and that the sanitary measures thus far taken have been ineffectual. It is said that the oyster beds along the coast, instead of being destroyed as the authorities ordered, were merely transplanted at some distance from the city, and that recently a number of fishermen who had eaten some of these oysters died of cholera.

The New Tuberculosis Directory of the National Association for the Study and Prevention of Tuberculosis, that will be issued soon, will list over 400 sanatoria and hospitals with a bed capacity of nearly 25,000; more than 300 special tuberculosis dispensaries and fully 450 anti-tuberculosis associations and committees. Since the first directory was issued in 1904, the increase in the number of agencies fighting consumption aggregates nearly 500 per cent. It will contain up-to-date lists of all hospitals, sanatoria, dispensaries, and associations engaged in the war against consumption. A summary of what has been done by the various State legislatures, and the county and municipal governing bodies will be included in the book. It will be the most complete report of the anti-tuberculosis campaign that has ever been published in this country.

The Rockefeller Institute.—On the day on which the new hospital of the Rockefeller Institute was thrown open to visitors, the Trustees of the Institute announced the further gift from Mr. Rockefeller of securities having a value of $3,800,000, to be added to the endowment of the Institute. This gives the Institute an income-bearing endowment of about six and a half millions of dollars.

New Chicago Hospital.—The cornerstone of the Iroquois Memorial Emergency Hospital on Market street, Chicago, was laid on October 15. The hospital is erected as a memorial to the victims of the fire in the Iroquois Theater on December 30, 1908. It will be four stories high, absolutely fireproof, and equipped in an up-to-date manner, with ambulances, ambulance rooms, surgical dressing rooms, operating and ward rooms, and nurses' and doctors' quarters.

Cornell University Medical College.—The opening session of the college was held on September 28, when 127 students were enrolled, distributed as follows: First year, 28; second year, 20; third year, 11; fourth year, 56; special students, 12. The decline in numbers from the fourth to the third year marks the falling off when the A.B. degree, with a full year's work in physics, chemistry, and biology, was required for admission to the college.

Nobel Prize.—Announcement is made that the Nobel Prize in Medicine for 1910 has been awarded to Dr. Albrecht Kossel, Professor of Physiology in the Medical Faculty of the University of Heidelberg.

Milk Commission in Philadelphia.—Mayor Reyburn has appointed the following commission to

investigate the milk supply of Philadelphia and to recommend regulations to insure its purity: Drs. C. Lincoln Furbush, Chas. B. Penrose, Henry Leffmann, Randle C. Rosenberger, Clarence J. Marshall, and S. McC. Hamill.

Physicians Long in Practice.—A reception was given, on October 21, by the Medical Club of Philadelphia, to twenty-seven physicians from various parts of the State who had been engaged in the practice of medicine for fifty years or more. Among the number was Drs. S. Weir Mitchell, J. Solis-Cohen, John B. Chapin, E. L. Duer, Benjamin Lee, and Wm. S. Janney.

Alvarenga Prize.—The College of Physicians of Philadelphia announces that the Alvarenga Prize for 1910 has been awarded to Dr. M. Katzenstein of Berlin, Germany, for his essay entitled: "The Formation of an Arterial Collateral Circulation in the Kidney." The next award of the prize, which amounts to $180, the income for one year of the bequest of the late Señor Alvarenga, will be made on July 14, 1911, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays may be upon any subject in medicine, must not have been published, and must be typewritten and sent to the secretary of the college, Dr. Thomas R. Neilson, on or before May 1. 1911. Each essay must be unsigned, but marked with a motto and accompanied by a sealed envelope having on the outside the motto of the paper and within the name and address of the author. The successful essay becomes the property of the college; other essays will be returned upon application within three months after the award.

Charitable Bequests.—By the will of the late Louise Drinen of Philadelphia, the sum of $1,000 is bequeathed to the Rush Hospital for consumptives.

By the will of the late Mrs. Mary Stinson Bean, the sum of $10,000 is set aside for the erection in or near the city of Norristown, Pa., of a hospital for children suffering from contagious diseases. The hospital is to be a memorial to Emily Stinson Bean, the daughter of the testator.

Dr. William J. Mayo was the guest of honor at a dinner given by the Medical Society of the County of Kings in Brooklyn, N. Y., on October 19. Dr. John C. MacEvitt, president of the society, was toastmaster, and the speakers included Dr. Newell Dwight Hillis, Dr. Lewis S. Pilcher, Father John L. Bedford, and Supreme Court Justice Luke D. Stapleton.

Dr. W. J. Burdell of Lugoff, S. C., has been appointed medical secretary for the Southern Division of the Esperanto Association of North America.

The New York Medico-Surgical Society held its annual meeting and dinner at the Hotel Manhattan on October 15. The paper of the evening, on "The Practical Treatment of Nervous People," was read by Dr. J. J. McPhee. Officers for the ensuing year were elected, as follows: *President*, Dr. J. A. Irwin; *Vice-President*, Dr. D. S. Dougherty; *Secretary*, Dr. Samuel McCullagh; *Treasurer*, Dr. J. Arthur Booth; *Member of Executive Committee*, Dr. John A. Bodine.

The Utah State Medical Association.—The sixteenth annual meeting of the association, which was held at Salt Lake City on October 3 and 4, concluded with the election of the following officers for the ensuing year: *President*, Dr. Fred W. Taylor, provo; *Vice-Presidents*, Dr. R. A. Pearse, Brigham City; Dr. W. B. Tyndale, Salt Lake City, and Dr. Heber C. Robinson, American Fork; *Secretary*, Dr. W. Brown Ewing, Salt Lake City; *Treasurer*, Dr. J. N. Harrison, Salt Lake City.

The Delaware State Medical Society.—The one hundred and twenty-first annual convention of the society was held at Wilmington, Del., on October 11. Officers for the ensuing year were elected, as follows: *President*, Dr. G. Frank Jones, Georgetown; *Vice-Presidents*, Dr. L. S. Conwell and Dr. William Wertenbaker; *Secretary*, Dr. G. W. K. Forrest; *Treasurer*, Dr. S. C. Rumford; *Counsellor for three years*, Dr. James H. Wilson. The next meeting will be held in Lewes.

The Minnesota State Medical Association.—At the annual meeting of the association held in Minneapolis on October 6 and 7, the following officers were elected for the ensuing year: *President*, Dr. G. W. Robertson, Litchfield; *Vice-Presidents*, Dr. F. W. Dimmitt, Red Wing, and Dr. F. W. Schofield, Benson; *Secretary*, Dr. Thomas McDavitt, St. Paul; *Treasurer*, Dr. R. J. Hill, Minneapolis. St. Paul was selected as the place for the next meeting which will be held on October 5 and 7, 1911.

Medical Association of the Southwest.—The annual meeting was held in Wichita, Kan., on October 12. The following officers were elected: *President*, Dr. M. L. Perry of Parsons, Kan.; *Vice-Presidents*, Dr. J. M. Griffin of Sulphur Springs, Ark.; Dr. W. H. Stuffer of St. Louis, Dr. E. S. Lain of Oklahoma City, and Dr. W. L. Alison of Fort Worth, Tex.; *Secretary-Treasurer*, Dr. F. H. Clark of El Reno, Okla.

The Second District Medical Society of Iowa, at its annual meeting at Davenport on October 11, elected the following officers: *President*, Dr. D. N. Loose, Maquoketa; *Vice-Presidents*, Dr. G. E. Decker, Davenport, and Dr. George Hoffstatter, Lyons; *Secretary-Treasurer*, Dr. J. V. Littig. The next meeting of the society will be held at Davenport in October, 1911.

The Minnesota State Sanitary Conference was held at Minneapolis on October 5. Dr. H. A. Tomlinson, superintendent of the State Hospital for the Insane at St. Peter, was elected president, and Dr. J. T. Gerould of the University of Michigan, vice-president.

The Late Dr. Andrew H. Smith.—At a regular meeting of the Academy of Medicine, October 20, the following tribute to the late Dr. Andrew H. Smith was read by the President, Dr. John A. Wyeth:

There died on April 8th of this year in the City of New York a distinguished physician who during the year 1903-4 presided over this body. For nearly half a century Dr. Andrew H. Smith was a prominent member of the medical profession of New York City, and it seems fitting in view of his long service and his high character that a formal and official notice of his death should be taken by the Academy of Medicine.

Graduating at the College of Physicians and Surgeons of this city in 1858, and taking a post-graduate course in medicine in Göttingen and Berlin, he returned to America just at the outbreak of the Civil War. He at once entered the army as Assistant Surgeon in the Forty-Third New York

Infantry, and was actively in service until 1868, when, having received the rank of Major by brevet, he resigned to take up the practice of medicine in this city. He was appointed physician to St. Luke's and the Presbyterian Hospital, and Consulting Surgeon at the Manhattan Eye and Ear Hospital.

Dr. Smith took a deep interest in the movement for post-graduate education in the United States, and was one of the original Faculty of the New York Post-Graduate Medical School and Hospital, and for many years Professor of Medicine in that institution. In 1902 he was elected President of the Medical Association of the Greater City of New York, and in 1903 of the New York Academy of Medicine.

It was my good fortune to have known this distinguished physician for many years, and it is enough to say that he was of that noble type of man whom one respected and admired more the more intimately one knew him.

The Late Dr. Brothers.—The Medical Board of the Beth Israel Hospital in special meeting assembled on October 14, 1910, unanimously adopted the following resolutions:

Whereas, after a period of deep anxiety and hopefulness for the recovery of our esteemed colleague, Dr. Abram Brothers, the sad tidings have reached us that death has claimed and taken him from among us, and *Whereas,* Dr. Abram Brothers, who, in the many years of our mutual contact, has become so endeared to us by reason of his sterling qualities as a man, his earnestness as a colleague, his devotion to his profession and contribution to its progress, has been taken from us at the height of a successful career, made so by his own efforts and ability, and which we had hoped to see continued that he might live to enjoy the retrospect, and see the fruits of his self-sacrificing labor and of the energy that he gave to the cause of humanity, therefore be it

Resolved, that we give expression to the feelings of heartfelt sorrow that overwhelm us on the occasion of his untimely death; that we feel that, by his departure in the prime of life and in his uncompleted career, the cause of humanity has lost an ardent advocate, the science of medicine a brilliant contributor, and the Beth Israel Hospital an earnest and able worker, and be it further *Resolved,* that we extend our most sincere condolence to his sorrowing family in this time of their sad affliction, for their grief is great in the loss of so loving a husband and devoted a father, who will live in their memory as Love and Goodness, and with us in his deeds and accomplishments, and be it further *Resolved,* that a copy of these resolutions be spread on the minutes of this Board, that a copy be sent to the bereaved family and that copies be forwarded to the medical press for publication.—Archibald E. Isaacs, David Robinson, Felix Cohn, Committee on Resolutions.

On the same date the Eastern Medical Society, of which Dr. Brothers was at one time president, passed similar resolutions of sorrow.

Obituary Notes.—Dr. James R. Berry of Columbia, Mississippi, a graduate of the medical department of Tulane University of Lousiana in 1880, died at his home on September 29, aged 54 years.

Dr. Cornelius G. Trow of Sunderland, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1872, a member of the Massachusetts State and Franklin County Medical Societies, died at his home on October 7, aged 63 years.

Dr. George F. Witter of San José, Cal., a graduate of the department of medicine and surgery of the University of Michigan, Ann Arbor, in 1856, ex-president of the Wisconsin State and Northwestern Wisconsin Medical Societies, a member of the American Medical Association and American Public Health Association, and of the California State and Santa Clara County Medical Societies, was struck by an automobile while crossing the street in front of his home, and died soon after, aged 80 years.

Dr. Adam Wenger of Concord, Ill., a graduate of the Department of Medicine of the University of Pennsylvania in 1866, a veteran of the Civil War, died at his home on October 10, aged 68 years.

Dr. Richard Leuschner of Mt. Clemens, Mich., a graduate of the Michigan College of Medicine and Surgery in 1892, a member of the American Medical Association, and of the Michigan State and Macomb County Medical Societies, and honary member of the Wayne County Medical Society, died at his home of pneumonia, on October 14, aged 52 years.

Dr. Joseph L. Romero of Jacksonville, Fla., a graduate of the University of Maryland School of Medicine in 1879, died at his home on October 14, aged 56 years.

Dr. Edna D. Timms of Portland, Ore., a graduate of the medical department of the University of Oregon, a member of the American Medical Association and of the Oregon State and Multnomah County Medical Societies, was instantly killed in an automobile accident on October 14, aged 41 years.

Dr. John A. Farnsworth of Fort Morgan, Colo., a graduate of the Colorado School of Medicine, Boulder, Colo., in 1897, a member of the Colorado State and Morgan County Medical Societies, and former Mayor of Littleton, Colo., died at his home on October 12, of heart disease, aged 39 years.

Dr. John C. Flynn of Warren, Mich., a graduate of the Cincinnati College of Medicine and Surgery in 1886, died at his home on October 15, aged 60 years.

Dr. Richard N. Beauchamp of Russellville, Ky., a graduate of the Albany Medical College in 1850, died at his home on October 10, aged 87 years.

Dr. David R. Greenlee of Minneapolis, Minn., a graduate of the department of medicine of the University of Pennsylvania in 1867, a veteran of the Civil War, died suddenly at his home on October 10, of heart disease, aged 78 years.

Dr. William W. Hamilton of Meridian, Miss., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1879, and of the New York Polyclinic Medical School in 1888, professor of obstetrics in the Mississippi Medical College, and a member of the American Medical Association, and the Mississippi State and Lauderdale County Medical Societies, and Health Officer of Lauderdale County, died suddenly while on a railroad train near Lafayette, La., on October 8, aged 49 years.

Dr. James W. Keath of Schaeffertown, Pa., a graduate of the Medical Department of the University of Pennsylvania in 1876, died at his home on October 15, aged 55 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF THE WINTER SESSION—INTRODUCTORY ADDRESSES AT THE SEVERAL SCHOOLS.

LONDON, October 7, 1910.

THE new winter's session is now at work. St. George's Hospital preserved the tradition of October 1 by opening on Saturday, but the others were content to wait until Monday of the following week.

The Middlesex Hospital had the good fortune to secure the presence of Viscount Kitchener to distribute the prizes for the past year, and this function naturally eclipsed the other part of this school's celebration. Lord Kitchener expressed a hope many of the students would join the Royal Army Medical Corps or the Indian Medical Service, and pointed out the good work open to them in either. He hoped enteric would soon be banished from barracks as effectually as cholera had been, but he seemed to have some misgivings that England was lagging behind other nations in prevention of disease and sanitation, particularly seeing what America had done in Panama. Referring to the military training that many are undergoing in the defensive force, he said those thus prepared would receive a warm welcome in the army. But they should remember that the training which turns out competent civil practitioners is quite inadequate in equipping them for the special needs of the army in time of war. Before they could be of real service to troops in the field they must go through a thorough training in the organization of the army and of the R. A. M. C., and also must obtain a knowledge of the conditions of camp and barrack life. Further, they should endeavor to acquire practical experience of the treatment of patients in the field, their collection in advanced hospitals, and of the system which must control their removal thence to general and base hospitals. All this would call on them for considerable sacrifice of time and energy, but in doing it they would have the satisfaction of knowing they were fitting themselves to be of real service to their country.

At St. Mary's Hospital Sir A. Conan Doyle distributed the prizes and gave a most interesting address. At the outset he disclaimed any claim to be regarded as a successful medical man and said an unkind chairman in America once remarked that no living patient of his had ever been seen. He assured them, however, that he could point to a few survivors. He gave his testimony to the extreme value of a medical education, even though one did not practise. It tinged the philosophy of life and furnished the whole basis of thought. The man with a competency would be wise to go through the medical curriculum. He would emerge with qualities which classics and mathematics could not give. There were, he admitted, some dangers, but in the great post-graduate course called Life he would learn to correct those weaknesses. One was undue materialism. He was educated in an age which looked upon mind and spirit as a secretion from the brain as bile was from the liver. Brain centers explained everything; if they could find and stimulate the center for holiness they would produce a saint, but if their electrode slipped on to the center of brutality they would evolve a Bill Sykes. That was, roughly, the point of view of the most advanced of the materialistic school.

He now saw clearly that frame of mind was largely a reaction against transcendental dogmas, so they confused two things which had little relation. He warned them against intellectual priggishness and said that not only had they never got to the end of a medical matter, they had not even reached the beginning of it, they had come to the middle with more or less empirical knowledge. With medical knowledge they had a little lantern of their own to turn on their general reading. In all directions medical facts threw light on customs and historical incidents. For centuries people wore wigs because a skin disease on his head made Francis I. of France cover it with artificial hair and his courtiers followed suit. The association of diseases with certain characters was a puzzling problem. Cæsar and Mahomet were epileptics and many other great men might be thought to be under suspicion of some disease.

History abounded with examples of the romance of medicine—a grim romance truly, but a realistic, absorbing one. This generation, Sir Conan Doyle thought, had brought greater change than any previous century. It was true that thirty years ago the microbic origin of zymotic disease was taught, but they did not expect so many minute organisms would be separated and that they would be able to cultivate these lowly vegetable growths as certainly as they grew watercress or green peas. In literary and dramatic romance the villain was innocuous as soon as he was unmasked. So in the romance of medicine they had been exposing the villain. When he had thus been exposed, microbe or micrococcus and his accomplice, rat, flea, or mosquito, the forces of law and order could then be turned upon him. Britons may well feel gratified that their countrymen have been protagonists in this war.

At St. George's Hospital Dr. Squire Sprigge presented the prizes and gave the address. He remarked that though the merits of the prize system were variously estimated no one had proposed to do without any kind of award. Some looked at education as a thing beginning and ending at a certain period, and from that point of view success in examinations was not a certain prelude to success in life. Medical education did not end with qualification, but in whatever branch they practised their life was one long education. Prizes and examinations were necessary when the State determined that they should not enter the profession until so far educated that they could take advantage of the greater and more comprehensive education of the rest of life. They were an incentive to this end, nothing more, and he protested against the multiplicity of examinations and their intricacy which had grown so much of late. He warned them against regarding knowledge for its own sake as of little account. The highest ranges of philosophical research seldom brought a monetary return. The simple way of righting that wrong would be the endowment of teaching. The short-sightedness and false economy of giving scholarships to students while making scanty provision for teachers was only an exhibition of the old, narrow view of education.

At the Leeds School this same subject, medical education, was discussed by Professor Marsh, who complained in his address of the overweighting of the curriculum. Medicine now rested, he said, on the four sciences of chemistry, anatomy, physiology, and pathology, and it was difficult for students

to keep pace with them. As a result many gained only a superficial knowledge from the mental surfeit supplied to them. He emphasized the need of a training which would develop the higher mental faculties. In examinations he had found intelligent and serious students showing deficient acquaintance with, for example, the essentials of surgical anatomy, owing to the fact that, having tried to learn a great number of details, they had learned nothing. The ideal teaching was to keep to essentials. The rejections at the Royal colleges had been 50 per cent., not that the standard was too high, but men had been struggling with an overloaded curriculum. Reform in this direction was urgently needed and Professor Marsh suggested that a conference be held of all interested to consider it in all its bearings.

University College secured a dean of the English Church to give an address, and he drew a parallel between the medical and clerical bodies. Both, he declared, set out after something more than mere materialism. Between the present and hereafter there was a bridge, thought—the "thought that wandered through eternity." Medical students should not let themselves become altogether immersed in the wonderful sciences they had to study. They should turn to mind culture. He prescribed a little bit of Wordsworth daily. From him they would learn that the heart was more than muscle and the eyes of a girl more than a study in optics. So it was more to be a man than a money magnate; it was useless entering the spirit world with a pauper mind. The dean (of Salisbury) suggested an eight hours bill for all professions and an age limit for retirement, so that all might pay homage to mental culture.

At the women's school Mr. Boughton of the Royal Free Hospital gave a lively address on the position of women in regard to the profession. He admitted their natural gifts were more suited for nursing, but held that if this were so with average women there were many in the highest degree fitted for medical practice. But he insisted that they must confine their work to their own sex. Among the differences between the sexes he offered explanations of some, but said he could not find out why a woman prefers a sharp chisel to a screwdriver for turning a screw or opening a packing case, nor why a woman usually began to turn the screw backwards, nor her strange dislike for oil, nor her tendency to give a bang to a mechanism that does not easily work. Such peculiarities, the speaker said, he was inclined to look upon as having some sexual basis.

At the London Hospital the Schorstein Lecture did duty for the introductory address, as did the Huxley Lecture at Charing Cross. King's College and St. Thomas's Hospitals confined their celebration to the annual dinner.

The School of Pharmacy opened its 69th session on Wednesday with an address by Mr. Howard, who traced its rise and progress. He hoped apprenticeship would not die out as it had done to the detriment of many callings. He deprecated the readiness of people to swallow powerful drugs on the recommendation of friends. In his young days medicines were "nasty," so people thought twice before taking them and often omitted to do so. He warned them against the fatal facility of the tasteless tablets. Well he might, for again this week fatal cases of poisoning by those products are reported.

LODGE PRACTICE.

To the Editor of the Medical Record:

Sir:—In last week's issue of the Medical Record there appeared an article on "The Lodge Practice Evil on the Lower East Side," which, judged from a literary standpoint, would be considered fairly good, but judged in any other light would fail to claim any recognition. The writer has eloquently set forth the evil, but has not intimated how this is to be remedied, if such is feasible. Doubtless he is an ardent advocate for its discontinuance, but this does not tend to remedy the evil in any way. The writer has a tendency to discriminate between good and bad physicians, academic and non-academic men. As a matter of fact, I venture to say that not more than one or two per cent. of all East Side physicians have academic degrees and this should not be a criterion to judge medical ability. The writer says that in former years physicians who possessed medical skill and knowledge were selected for the positions, the truth being that very few physicians desired lodge practice, and as a result physicians had no difficulty in becoming lodge doctors.

If the writer would suggest a means for the uplifting of traditional medical ideals, instead of calling his colleagues young, ambitious tyros, he would be rendering an inestimable deed of good to the East Side physicians.

Progress of Medical Science.

Boston Medical and Surgical Journal.

October 13, 1910.

Acute Thoracic Empyema. Avoidance of Chronic Empyema. Rib Trephining for Suction Drainage. S. Robinson.
Scoliosis. E. H. Bradford and R. Soutter.
On the Absorption of Protein and Fat in Pulmonary Tuberculosis. A. E. Austin, M. Ordway and R. Montague.
A Rapid Presumptive Test for Diarrhea Caused by the Gas Bacillus. A. I. Kendall and R. M. Smith.

Empyema.—S. Robinson emphasizes the fact that while nature strenuously combats pleural infections in spite of one's incomplete efforts, accuracy of diagnosis, prompt surgery, and diligent after-treatment are necessary not only to save the patient but also to shorten convalescence, to prevent amyloid disease of other organs, and to restore the normal function of the lung and pleura. Abscess of the periphery of the lung, if early recognized and operated upon, might avoid a local empyema. Prompt detection of local empyema often prevents occurrence of general pleural infection, and chronic empyema is a condition that should never exist, being attributed to neglect of early recognition, in operative treatment, or in post-operative management. Re-expansion of the lung is frequently impossible in these neglected cases owing to adherence of the lung. There is a difficulty that attends the diagnosis and localization in certain cases. Cases are reported of spontaneous cure of empyema by rupture into a bronchus. One must not overlook the possible diversity of origin of empyema by lymphatic extension, abscess of the liver, subdiaphragmatic abscess, and perforated duodenal ulcers not infrequently lead to this condition, with or without perforation of the diaphragm. It also occurs by blood metastasis in scarlet fever, measles, typhoid, whooping cough, and other systemic infections. The *x*-ray is a contributing, though unsatisfactory means of diagnosis of purulent pleurisy. In a localized empyema drainage and obliteration of the small cavity need alone be thought of. In a second group of cases in which the acute stage has been neglected and the pus allowed to remain undrained

for a longer time, the author advocates in the early cases a persevering maintenance of the suction provided by the chest wall, which is at least partially accomplished by a gauze dressing and a binder and better by a mackintosh dressing. Numerous devices have been employed in the drainage of empyema, all of them embodying one of three principles—siphonage, suction, and valvular action. Intercostal trocar puncture, and rib-section with or without the use of a rubber collar, constitute the two main divisions in the method of thoracotomy. Leakage is the chief fault of these methods. The permanency of the air-tight closure is the crux of the situation. To attain this permanent air-tight suction, the author advocates a method of rib-trephining, which he has employed in cases of the first and second groups with great success. After trephining a rib he inserts a metal tube with a thread cut on one end and corrugated for the attachment of rubber tubing on the other. As a safeguard against the ill-effects of sudden pneumothorax in patients susceptible to it, differential pressure may be used. The author has employed a positive pressure cabinet in three cases and has always had apparatus at hand to use if necessary. Rib-trephining obviates the possibility of pneumothorax.

Scoliosis.—E. H. Bradford and R. Soutter state that the essentials in treatment of this condition are as follows: (1) A careful examination of the condition of the back, not only as to the curves and contour, but also as to the normal rigidity and lack of strength of the back muscles. (2) Where needed, the use of such exercises as will strengthen the muscles, and such flexibility exercises as will correct abnormal stiffness. These flexibility exercises must be carefully applied so as to stretch at the part of the maximum stiffness, and not increase the flexibility of the flexible portions of the spine. (3) In the more severe cases the constant use of some form of pressure appliance, with the pressure applied to the convexity of the curve, and without pressure on the concavities. (4) These cases need oversight and direction at stated intervals during a long period. That is, during the rapidly growing years such oversight and direction should be given by some one familiar with the course of affections of this class. Such patients also need the constant direction of a parent or nurse or physician who will enforce strict and persistent attention to the details of treatment, and of a family physician who will pay attention to the observance of the laws of health, diet, metabolism, etc. (5) The affection is not to be regarded as a disease, but as a fault in growth, and for this reason care is needed for the patient during the growing years. The combined efforts of a family physician and expert specialist are of benefit in cases with this distortion and gratifying results may be expected to reward persistent efforts.

Protein and Fat Absorption in Pulmonary Tuberculosis.—A. E. Austin, M. Ordway and R. Montague found that the percentage of loss is much greater when the nitrogen intake is small than when it is large; with a diet containing a large amount of nucleoproteids like liver and sweetbreads the comparative nitrogen loss is much greater. The percentage of loss of fat also follows the same law as that of protein; that is, as the amount of fat taken increases, the procentual loss becomes less and less up to a certain point, which has apparently never been fully determined. The melting point of the fat also affects its absorption; the fluid oils are much more absorbable than the solid fats and, what is more important, the addition of a fluid fat to a solid one increases the absorption of the latter. The amount of free fatty acids also tends to increase the absorption of fat, but the suggestion of von Mering that free oleic acid be added to fats is not absolutely necessary, since as far as is known the healthy intestine is able to hydrolize fat in unlimited quantities, nor is this power apparently lost in those chronic cases where cod liver oil is used. Even where the steapsin is diminished or lacking through disease of the pancreas, the intestinal bacteria seem able to split a large proportion of the ingested fat. It is only in forced fat feeding that the inability to split the fat would seem to be suspected, and here, where fat to the extent of 425 gm. daily was ingested there appeared no great increase in the percentage of loss. Cod liver oil, which has no inherent value in phthisis, but which must have had some basis for its long popularity, probably acts on account of its low melting point. This admirable absorption of nutriment under the regimen of the sanatorium treatment of the tuberculous, although such enormous amounts of food are given, is probably due to two reasons: First, the ration is well balanced, and it is well known that under this condition the absorption of any one form, protein, for instance, is much better when given with a corresponding quantity of fat and carbohydrate than when given alone in large quantities; secondly, the human body, provided that the intestinal tract is normal, absorbs nourishment according to its needs, much as a sponge takes up water according to the state of dryness existing within it.

Speech and Voice Defects and Their Treatment.—A. Myerson states that a certain proportion of functional aphonia, greater than most laryngologists recognize, is due to misuse of the entire speech apparatus and not to changes in the larynx. It is necessary to emphasize the fact that the entire apparatus is misused in these abnormal speech efforts, just as it is normally used in its entirety in normal speech effort. Diaphragm, chest, and larynx are all involved in the spasticity—but the larynx suffers most. Moreover, inflammatory and other organic changes in throat and larynx which are associated with pain and hoarseness are often not the causes of the changed functioning of the parts involved, but with the pain and hoarseness are symptoms of the wrong use of the parts. Medical science is adding to the cellular interpretation of disease, the physiological or dynamic interpretation, and therapeutics can most profitably apply the lessons of pathology. The method of using any part that is normally operated by the will can be changed if it be a wrong method to a correct one, at least in most cases. With that change will come a readjustment more or less complete of the parts to the normal. This is as true in laryngology as in orthopedics, and its recognition has an important hearing on the therapeutics of the future.

Test for Diarrhea Caused by Gas Bacillus.—A. I. Kendall and R. M. Smith describe a rapid presumptive test by means of which diagnosis of diarrhea due to an infection with the gas bacillus can be made within twenty-four hours.

A Case of Hyperchlorhydria Apparently Relieved by the Use of Prisms. C. J. Astle.

The Mechanicobiological Standpoint in Medical Problems.—J. Wright in discussing some of the problems of surface tension, states that it is the interchange of material through cell membranes, watery material, albuminous fluids, colloid solutions, living colloid bodies with their own marked surface energy—it is the osmosis between cells in the cryptal tonsillar phenomena of infection, which are bound up with the streaming of kations and anions, de-

tected by the electrometer and which interests us in physiology and pathology. It is the alteration which these ions make in the tensile state of the surface of the inter- and intracellular colloids, which determines what shall go in and what shall stay out in the process of surface infection and surface immunity. Recent work has fully justified the growing suspicion that it is the electric charge on the lipoid constituent of corpuscles and fluids, and not the other chemical constituents of the protoplasm, which is chiefly responsible for the serum reactions, so puzzling, especially at present, in the study of the syphilitic infection. It has been fairly well established that a phagocyte flows around a bacterium or a carmine granule as a drop of water spreads freely over a wet surface, while both refuse to do so if the bacterium or glass surface has not the proper surface tension. The author believes that all this shows that one is drawing away from the biochemical concepts of Ehrlich.

Nervous Affections in Relation to the Adjustments of the Eyes.—G. T. Stevens presents as the first of a series of studies on this subject, a report of a case of chronic progressive chorea. He had, many years ago, announced the proposition that chorea is due to faulty eye adjustments and principally to hypermetropia, and he is now better prepared to defend this position. This case was one of violent chorea which had been continuous for fourteen years, long enough to be regarded as chronic, and one to the relief of which the best efforts of able physicians had been directed without avail. Correction of the abnormal adjustments of the eyes, mainly of the declinations, caused at first a rapid and then a steadily progressive improvement.

Methods of Cancer Treatment.—J. W. Vaughan classifies the two methods of approach in cancer treatment as follows: (1) Local, including all surgical procedures, the local application of caustic ointment, zinc chloride, arsenic, and other chemicals, including the use of trypsin and thymus preparations, as well as the various methods of freezing superficial growths, the *x*-ray, radium, and electricity. (2) General methods, through the agency of the blood stream, including the use of Coley's mixed toxins, the employment of various drugs, the use of ascitic fluid obtained from a recovered case, as reported by the late Dr. Hodenpyl, and the use of radium and the *x*-ray. To this class the author adds the injection of cancer residue. Two facts are well established: first, the body in exceptional cases may of itself destroy all cancer cells; and, second, this tendency is shown in almost every case, by means of periods of lessened rapidity of growth of malignant tumors, and sometimes actual decrease of their size, after which growth recurs with renewed vigor. The work of V. C. Vaughan on cellular proteids has demonstrated that any proteid cell may be split into two definite chemical parts by heating the proteid in a 2 per cent. solution of sodium hydrate in absolute alcohol. One portion, which contains the toxic radical, is soluble in the alcohol, and the other portion, which is insoluble, is termed the residue. When the purified toxic portion is injected into animals we obtain no immunity to the entire cell, but only a slight tolerance to the toxin itself. The residue, which is insoluble in the alcohol, is soluble in water, and when this portion of the proteid cell is injected into an animal that animal becomes to a certain degree immune to the injection of the entire proteid, if the latter is a living bacterial cell. In other words, the residue contains the specific chemical group that distinguishes that proteid from any other proteid. The author reports a case of carcinoma uteri in which the patient had been confined to her bed for a period extending over four months. Three weeks after injections of residue prepared from a breast cancer were begun, she was able to be up and about the house. Four months after treatment was started she was actively engaged in household duties, had gained twenty pounds, and made frequent trips out of the city. Within from twenty-four to forty-eight hours following a residue injection the percentage of polymorphonuclear elements falls from 5 to 40 per cent., while there is a corresponding increase in the percentage of mononuclear cells. Thus it appears that while the polymorphonuclear cell is the chemical laboratory in which the specific ferment is formed in the case of bacterial infections, the mononuclear cell is the essential element when dealing with altered autogenous cells. Thus one can reason that with every method of treatment proposed for malignant conditions in which there is some degree of destruction of the cancer cells, the resulting chemical changes necessary to bring about the removal of the dead cellular elements will cause a certain percentage of ferment to be formed which will be available for the destruction of a given number of living cancer cells.

Autogenous Vaccines in Ear Suppurations.—S. J. Kopetzky states that it is impossible to draw final conclusions from his small number of cases, but because they were selected to represent groups of middle ear suppurations, the results thus far obtained are worthy of note. The uniform failure to effect any results in the cases with bone lesions was logically to be expected. The study has, on the other hand, shown that autogenous vaccine therapy has a field of usefulness in otology in properly selected cases; that is, among such where the subsidence of bacterial activity means the end of the lesion. In acute cases, after the period of violent onset and its co-existing constitutional reaction has subsided, the added immunity acquired through vaccine therapy seems to rapidly cure the diseased ear.

Carbolic Acid Poisoning.—G. B. Burke reports a case of this condition and gives in detail the treatment that he has found most effective.

Dwarf Tapeworm.—C. C. Bass and J. M. Gage report fifteen cases of this condition, to further emphasize the fact that infection with this parasite is common in the Southern States.

Relation of Hospitals to Public Health.—H. W. Austin states that the intimate relation of the hospital to public health is perhaps more frequently shown in the United States Marine Hospitals than in any other class of hospitals.

Hypopituitarism.—E. S. Cross reports a case which he attributes to deficiency of the pituitary secretion. The salient points were normal mentality, small stature, striking adiposity, hypotrichosis, amenorrhea, and infantile genitalia.

Hyperchlorhydria Relieved by Prisms.—C. J. Astle states that hyperphoria is one of the many reflex causes by which a marked change is effected in the amount of gastric secretion, and describes a case in which the wearing of prisms relieved the hyperchlorhydria.

Neurology and Preventive Medicine.—J. Collins believes that poliomyelitis and epidemic cerebrospinal meningitis should be considered reportable, quarantinable diseases. It is of special importance to recognize the atypical cases of the former which may spread the disease as well as the others. Other infectious nervous diseases which come within the scope of the neurologist are epidemic polyneuritis and pellagra. Preventive medicine has not given the attention that it should to certain occupational diseases, especially of workers in foundries, glass factories and rolling mills. He specially mentions a generalized intoxication of the system in the bronze worker and refers particularly to the effect of dry heat in producing nervous trouble. Workers in these lines should be safeguarded. The latter part of his article is devoted to the subject of psychoneuroses, and he considers the theory of Freud, that these have a sexual origin, deserving of the most careful investigation and consideration. He goes at some length into the explanation of this theory and its applications to the study of the etiology of the various neuroses, including, besides hysteria, the obsessions and phobias which Freud traces back to the same origin. While the treatment of psychoneuroses must be dealt with from a pedagogical standpoint, physicians must devise ways and means for giving the instruction.

Cystadenoma of the Kidney.—G. E. Shoemaker reports a case presenting an unusual series of symptoms, viz., uterine myoma with hemorrhage, spinal caries, and kyphosis, together with a large bleeding tumor of the kidney. Hysterectomy was performed for the uterine tumor and two weeks afterward the hemorrhage from the kidney, which had ceased, recommenced and became serious, and since no chance of infection through the bladder could be taken a vesicovaginal outlet was made for removal of clots and for irrigation, leaving a clean field for the kidney operation. The kidney tumor, removed through a dorsal incision, was roughly in the shape of the kidney, which was mostly replaced by it. The tumor was composed of fine strands of connective tissue apparently growing out from the cortical connective tissue and extending in a branched papillomatous manner in all directions. The diagnosis was papillomatous cystadenoma of the kidney without definite malignancy.

Tonsil Snare.—C. F. Welty describes and illustrates a new combined forceps and tonsil separator which has the advantages of being strong, locked together instead of having screws, and hence is easily kept clean, is easily and quickly threaded, and has a new device for fastening the wire, which, once clamped, tightens it the harder it is pulled.

Mammary Hypertrophy.—H. Albert reports the case of a girl aged thirteen in whom both breasts weighing about twenty-five pounds each, were amputated. From a consideration of the pathological findings and review of the reported cases, the author says that diffuse hypertrophy of the mammary gland is to be looked upon as a simple hypertrophic process, involving all the elements of the gland, but especially those that are most actively growing at the time. It is probably due to the activity of the same hormones that produce the physiological enlargements.

Mistaken Diagnosis.—A full report of this article appeared in MEDICAL RECORD, Vol. 77, page 1030.

The Electrocardiogram in Diagnosis.—L. F. Barker, A. D. Hirschfelder, and G. S. Bond call attention to the value of determination of the electric variation accompanying the movements of the heart in diagnosis. These have an intensity of from 0.001 to 0.003 of a volt and therefore could not be studied accurately until an extremely delicate galvanometer had been invented. Such a one has been contrived by Professor Binthoven of Leyden. It can be used to study very small currents and even .001 of a volt is sufficient to cause a marked deflection of the galvanometer. The electric changes during each cardiac cycle are characteristic and correspond to the successive contractions of the auricle and ventricle. The base becomes negative before the ventricles and gives rise to a typical wave due to the auricular contraction which is followed by another due to the ventricular contraction. The most recent investigations of Kahn in Hering's laboratory have shown that the electric variation and the contractions are absolutely synchronous and that the electric variations do not precede the contractions as was at first supposed. The normal electrocardiogram is illustrated and explained, but it undergoes a very definite change with hypertrophy of the left ventricle, the first ventricular wave becoming inverted. It is also particularly useful in diagnosis of heart block.

Rachitis.—J. W. Van Derslice says that rachitis is a diet disease, but he cannot subscribe to the opinions that have attributed it mainly to the arrangement of the percentages of the different constituents of the food. There are rachitic infants who are fed entirely on breast milk, and the point should be emphasized that, while many cases show this and that contributing cause, in all there is an indigestion which is always present. The digestive symptoms always precede the bone changes, but sooner or later the latter appear. Besides these, there are general muscular feebleness, nervous irritation, enlarged lymph glands, disorders of dentition, and blood changes like those in chlorosis, especially in the severe cases, and a general tendency to catarrhal disorders. The disorder is an insidious one in its onset and the definite clinical symptoms of restlessness, slight rise of temperature at night, profuse perspiration about the head and face, general tendency to tenderness on handling, flatulence and bowel disturbance, either diarrhea or constipation, always precede the bone changes. The term acute rachitis is not applicable, nor is there any definite disease that may be called chronic rachitis. Of the more frequent mistakes in diagnosis, one is the failure to recognize inflammatory and bloody effusions under the periosteum, and this is undoubtedly the cause of the use of the term acute rickets. Another is mistaking the bone changes of congenital syphilis for those of rickets, and still a third is that of considering the pseudoparalysis of rickets as essential paralysis. Infantile scurvy may complicate rickets, but the two conditions are distinct. Children rarely die of rickets *per se*, some intercurrent disorder is the cause of death, especially disease of the lung. The treatment consists in attention to diet and hygiene. In breast-fed infants something should be done to make the mother's milk suitable, and it may be necessary to supplement with artificial food. No diet can be recommended in all cases. There is danger of putting too much stress on the fat diet in these cases. Syrup of iodide of iron is sometimes indicated. The addition of malt and molasses sometimes gives favorable results for the digestive weakness. The intercurrent disorders should be attended to, as well as avoidance of strain on the weakened bones to prevent deformity and help Nature's efforts at repair.

Bowel Surgery in Children.—S. G. Gant gives his experience in 368 cases of bowel surgery in children, in a class of cases which he thinks are sometimes neglected or unrecognized. The time has arrived when physicians should assume the responsibility of treating the anorectal affections of children as soon as diagnosed. This does not always mean an operation, for in many cases a cure can be effected by regulating the bowels and by topical applications. Surgical intervention when necessary should

cause no anxiety, since in the vast majority of cases it can be easily performed, is devoid of danger, the postoperative suffering is slight, and convalescence is short. Several tables are given showing his results, and the special points of technique are briefly mentioned. The age of the patients varied from birth to 12 years, the majority being over 6. The five deaths that occurred are not attributable to the operation. About one-half of the constipated infants and children examined suffered from mechanical obstruction of some kind, and he thinks that such conditions are much more frequent than is at present recognized, occurring in about 25 per cent. of cases. He describes a new method of enterocolonic irrigation by cecostomy.

Genital Tuberculosis.—This paper was reported in MEDICAL RECORD July 2, 1910.

A Forecast of the Pharmacopeia.—M. I. Wilbert reviews the principles and ideals that have been evolved in the various revisions of the pharmacopeia from the time of its foundation.

Bloodless Operation for Hemorrhoids.—L. J. Hirschman describes his technique in performing this operation, under local anesthesia with a 1 per cent. solution of quinine and urea hydrochloride.

Pernicious Anemia.—B. P. Rosenberry describes a typical case of the severe type of this disease, which illustrates the remissions which are so characteristic of the condition and also the manner in which the condition for the time being responds to arsenic.

Adiposis Dolorosa in Mother and Daughter.—A. H. Carroll reports two new cases which shed no new light on the etiologic factors or treatment.

Anaphylactia.—L. K. Hirshberg states that persons subject to urticarial eruptions from a definite food may be regarded as sensitized to that protein. These phenomena may be congenital, acquired, or inherited.

Accessory Renal Arteries.—D. N. Eisendrath and D. C. Strauss direct attention especially to the possibility of severe hemorrhage occurring from such accessory vessels, either during the performance of nephrolithotomy or after the patient has returned to bed. No doubt many cases of serious and in some cases fatal hemorrhage have been due to bleeding from such accessory vessels, especially those passing to the upper or lower poles. In future it would be advisable, before incising a kidney for the removal of renal calculi or performing a nephrectomy for any condition, to examine the upper and lower poles and the hilum of the kidney for the presence of any supernumerary arteries. If such vessels are found, it is advisable to ligate them separately from the main renal pedicle.

Gangrene of the Lung.—C. C. Dolley reports a case of this condition in which the trichomonas was the only discoverable etiologic factor.

The Non-Oviparous Female Hookworm.—W. Litterer is of the opinion that the non-oviparous nature of the female hookworm is not entirely due to the old age period, but is, in all probability, caused by some defects in development, or occasioned by peculiarity in a given strain.

Cultivation of Tissues Outside of the Body.—A. Carrel and A. T. Burrows in an attempt to discover the laws underlying the generation, growth, and evolution of cells, took their cue from the method recently employed by Harrison in observing the development of nerves from the central nervous system of frog embryos cultivated in a drop of lymph. Later Burrows had adapted this method to the embryonal tissues of warm-blooded animals. Their experiments consisted in removing small fragments of tissue from frogs, cats, and dogs, and inoculating them aseptically into a plasmatic medium, taken from the same animal, and sealing the materials in hollow glass slides, which were then kept in an incubator at 37° C. By means of a microscope placed in a thermostat and kept at this temperature, they were able to observe not only the growth of cells, but also their multiplication. They found that the cultures of the different tissues possessed common characteristics, the beginning of the cellular proliferation depending on the nature of the tissue, the age of the animal, and other factors. Thus, in glandular organs of adult dogs the vegetation started after thirty-six or forty-eight hours. Cultures of thyroid, kidney, and suprarenal are in full activity four or five days after the inoculation. The first indication of the growth of tissues is the appearance on the edges or surface of the specimen of a few small and regular granulations, consisting of the cellular cytoplasm in which nucleus and nucleolus are soon visible. In all the tissues there appear, at first, spindle cells, and at the same time, or a little later, appear polygonal or multipolar cells, whose morphology varies widely according to each tissue and organ. A piece of cartilage had in the course of nine days generated outside of the body a piece of new cartilage two millimeters long. In the cultivation of organs the most striking results were obtained in the case of the kidney. In a culture of fragments of kidney tissue obtained from a cat, on the sixth day the cells were observed to have proliferated with the formation of tubes lined with epithelial-like cells, and having the appearance of renal tubules. In a second series of experiments these investigators were able to modify the rate of growth of tissues by passing them into a second medium. By this method they succeeded in reactivating pieces of thyroid tissue, so that the thyroid of an adult animal became as active as the thyroid of an animal a few days old. According to the authors this method may render possible the cultivation of certain microorganisms in conjunction with living tissue cells or alone in plasmatic media. They assume that the perfection of this method will be helpful in the exploration of unknown fields of human pathology.

Hereditary Aspects of Mental and Nervous Diseases.—F. W. Mott states that the Mendelian doctrine of dominant and recessive characters explains why a characteristic feature of a particular grandparent which was not visible in the parent reappears in the child. It also accounts for those heritable diseases and abnormalities which are transmitted by the females in ancestry and appear in the males, *e.g.* hemophilia, Daltonism, pseudohypertrophic paralysis. Nonexpression of a disease does not imply noninheritance of a disease, rather a predisposition to disease. A hereditary tendency to nervous disease may have different expressions in successive generations, *e.g.* insanity and epilepsy; the hereditary transmission of nervous or mental disease is rather of the nature of a neuropathic tendency, the character of the disease being largely determined by the exciting cause. As regards the large question of Mendelism in relation to human inheritance, the author has not met with any cases in entire support thereof in the study of the hereditary aspect of nervous and mental disease. Heredity plays an important part in myotonia congenita, pseudohypertrophic paralysis, progressive muscular dystrophy, the neuritic type of progressive muscular atrophy, hereditary ataxia, Huntington's chorea, and family periodic paralysis.

Mitral Stenosis.—A. Morison reports a case of this condition, which exemplifies the existence of unsuspected valvular disease. Mitral stenosis is very frequently overlooked. In this patient an attack of tonsillitis induced an arrhythmical action, which suddenly blazed into a short and sharp tachycardia, which subsided as suddenly as it arose. These sudden explosions of erratic action have been regarded as mainly of neural origin. Recently a myogenic theory has been advanced, as in the conception termed by Lewis fibrillation of the auricle as the cause of irregularity of the heart. The author inclines to the neurogenic theory and states that the disturbances of cardiac motion are induced by exertion, emotion, or reflex irritation. He dwells in this case on the physical signs, which were the absence of bruit in the tachycardial heart, the triple rhythm audible at the apex, the socalled crescendo murmur, and the arrhythmia.

Collapse of the Lung.—W. Pasteur reports five cases which he regards as clear examples of active lobar collapse from reflex inhibition of the diaphragm, occurring most probably in otherwise fairly healthy lungs, and in the absence of inflammatory lesions of the diaphragmatic pleura or peritoneum, such as are almost invariably found in fatal cases of the condition after surgical operations on the abdomen. As to the cause of active lobar collapse in these cases the following points are noted. 1. The cases of diphtheritic paralysis quoted prove that arrest of diphragmatic movement does cause massive lobar collapse of the lung. 2. An entire series of fatal cases (other than those due to paralysis) have, without exception, this feature in common—namely, the existence of a powerful source of irritation in the neighborhood of the diaphragm within the area supplied by the vagus—that is to say, a condition of things in which reflex inhibition of that muscle might very readily be set up. 3. In four out of five cases the lung affected is on the same side as the operation wound. 4. The disappearance of apex beat and heart sounds from the normal position and their displacement toward the affected side. 5. The sudden overdistention of the unaffected lung. 6. The almost complete silence over the affected lobe. The initial symptoms closely resemble those of pulmonary apoplexy. The onset of active collapse is preceded by a prodromal period of some hours in which the patient looks and feels ill. The temperature rises gradually and there may be slight distress of breathing with some duskiness of surface. Then occur sudden dyspnea and cyanosis, and occasionally pain, cough, and expectoration. There is immediate loss of mobility on the affected side of the chest, with loss of breathsounds. The healthy side of the chest presents the usual signs of compensating hypertrophy. The acute symptoms are of short duration, and the lung resumes its functions within a few days.

606.—W. E. Home reviews the history of this remedy and describes his own impressions as to its value from observations made in Berlin and Frankfort.

Congenital Pyloric Stenosis. R. Hutchison.
Prizes and Performances. S. Squire Sprigge.
Woman's Sphere in Medicine. E. W. Roughton.
The Evolution of Surgery. W. Thorburn.

Hereditary Aspects of Nervous and Mental Diseases.—See abstracts of articles in the *Lancet* of Oct. 8, 1910.

Congenital Pyloric Stenosis.—R. Hutchison states that the term "congenital" assumes as proved a disputed point in the natural history of this disease, which exhibits clinical and pathological problems of the most interesting and baffling character. Eighty per cent. of all cases occur in boys, and there is a relatively large proportion of firstborn children affected with this disease. There is noted the frequency with which the children of doctors are affected. The most prominent symptom is persistent vomiting which tends to cease for some hours with any change of food and to recur as violently as ever. There are pseudoconstipation (due to failure of food to get into the intestine), rapid loss of weight, and progressive emaciation. The child is not anemic but simply looks starved. The physical signs show a dilated stomach and waves of visible peristalsis. A pyloric tumor may be felt to the right of the middle line. As to the pathology two distinct views are held, namely, that the thickening of the pyloric canal is to be regarded as a congenital malformation, and that it is due to overwork, the consequence of a long-continued spastic contraction. The author inclines to the latter theory. Of twenty cases that he had seen in private practice, seventeen had been treated at home; all of these recovered without operation. Of the three sent into the hospital for treatment two died. Others have had similarly favorable results, which are not equaled by those of surgical treatment. The essentials in treatment are careful feeding and daily lavage of the stomach. Small amounts are to be fed at frequent intervals. Continuous poultices should be applied to the epigastrium. Drugs are of little help, but the only one which has ever seemed to be of any use is opium. Operation is to be advised upon those cases that do not show any improvement after a lapse of three to six weeks.

Prizes and Performances.—See editorial in MEDICAL RECORD Oct. 15, 1910, page 677.

Woman's Sphere in Medicine.—E. W. Roughton describes the suitability of medicine as a profession for women, and discusses, as bearing upon this question, the subtle differences of sex.

The Evolution of Surgery.—W. Thorburn states that in 1884 it had been thought that finality had been reached in the manipulative art of surgery. Few foresaw the rapid evolution of the new surgery which the work of Lister had already inaugurated. Adenoids and appendicitis were then practically unknown. The abdomen was opened with fear and trembling, and abdominal operations were performed only in the hope of averting directly threatened death. In comparing the records of to-day with those of 1883, of the Manchester Royal Infirmary, the author notes that in the earlier year there were but twelve operations on the abdomen, of which seven died; while in 1908 there were performed five hundred of such operations, with a mortality of about 11 per cent. The same disparity is noted in the case of renal and breast surgery. In 1883 one-sixth of all the operations performed were amputations of which one-sixth died. In 1908 only one operation in fifty was an amputation, and the death rate had fallen to one in twenty-five. These figures eloquently attest the advantages of modern conservative surgery in the saving of limb. In 1883 there were only three hernia operations, while in 1908 they were performed 264 times. In the earlier days every wound required a daily dressing; to-day the operations are left untouched for a week. Surgical advance is the result of two great discoveries, anesthesia and asepsis. The hurried and brilliant surgery of bygone days is past; the perfection of asepsis has given the mechanical art of surgery a freedom of action and an exposure of the operative field that were formerly incredible. The extension of operative treatment has demanded and obtained an accuracy of diagnosis which was formerly not required and not obtained. A quarter of a century ago all or nearly all of acute diseases of the abdomen were fatal, death being assigned to peritonitis. The advance in surgery has called for the early diagnosis of all the causes of peritonitis, and to-day the diagnosis can be made. In 1876 Lawson Tait first removed stones from the gall bladder; in 1909 Mayo Robson had collected 3,000 of such operations performed by three sur-

geons alone, with a mortality of less than 2 per cent. Gastroenterostomy has rescued many thousands from the slow martyrdom of so-called dyspepsia. In 1896 Farina made the first attempt to suture a wound of the heart itself, and in 1909 Vaughan collected 150 cases, with 35 per cent. saved from certain death. Among the greatest dangers of modern surgery, one may discern a tendency to operate too early, and without due care for preliminary diagnosis. A closely allied danger is that of extreme specialism, which is another term for limitation of thought.

Pupillary Disturbances in Dementia Præcox.—Meyer discusses this subject briefly, omitting all reference to the work of French and American authors. He evidently means to do little more than report three cases of dementia præcox in which the pupillary phenomena were of the same character. The cases are of further interest as exhibiting many somatic alterations believed to form a basis for the psychical phenomena. This common behavior of the pupil was as follows: Pressure on the iliacal point caused a dilatation, which remained fixed when light was exhibited. When the pressure was removed the pupils contracted, but still reacted to light. This reflex has naturally suggested a close connection between dementia præcox and hysteria. The two conditions further furnish many symptoms in common, while others which are almost essentially hysterical are absent in dementia præcox. As is well known the pupillary symptoms of hysteria are very extensively discussed in monographs, but all attempts at finding a typical quasi-constant hysterical pupil seem to have ended in failure. No doubt the pupil has its own peculiar anomalies, explicable by pathological physiology, which are in evidence in a number of neuroses, which while possessing many points in common, are nevertheless distinct affections (epilepsy, hysteria, dementia præcox, etc.).

Neuroses of Infants Including Inability to Chew.—Hochsinger calls attention to the fact that yearlings and even two year olds without pylorospasm are still unable to nurse or drink. As these phenomena are peculiarly nervous in character they may be termed hysterical. Close study of these cases reveals other phenomena which are properly classed as hysterical. The inability or refusal to take food suggests hysterical anorexia or anorexia neurosa. The author sees a close connection between these phenomena in the nursling and the weaning period. The act of weaning, in fact, may impose itself upon the child of neuropathic inheritance as a series of psychic traumata which may be expressed by the usual motor and sensory phenomena of hysteria. This anorexia may lead to trophic results if continued. Nutritional neurotic disturbances in older children have been much more widely discussed, especially as regards dystropric change. The chief mechanism or expression of nutritional neuroses in children aged about from three to five years is inability to chew properly. The children cannot undergo the drudgery, so to speak, of mastication. When does the impulse to chew originate? If a finger is introduced into an infant's mouth, either sucking or biting movements are set up. The author's experience is that the biting act should succeed the suction act at about the twentieth week. This means that the child has a normal impulse to chew at the age of five months on the average. Precocious and tardy exceptions naturally exist. The chewing act is complex in character, the lips, tongue, and gums all being involved, along with the swallowing muscles. From another viewpoint chewing should begin with the eruption of the back teeth; at all events these teeth should be developed when the impulse to chew first appears. The entire apparatus involved is so complex that any disturbance in the cortex cerebri must affect it. Disorder in the foreordained state of affairs is exhibited in such phenomena as salivation, choking, and vomiting—in other words nervous anorexia. Children thus affected have an abnormal tendency to suck the thumbs. A vicious circle is set up by the hysterical or neuropathic condition of the mothers of these children, who fear that the latter are bound to starve. The author's remarks which follow are of interest but must be neglected both for reason of space and because his work leads to no fixed conclusions.

Homesthesia.—Sellei has coined this word in connection with a demonstration to show that an individual, under certain circumstances, is as sensitive to his own albuminous fluids as he is believed to be toward the fluids of others, whether human or animal. That is to say, if albuminous fluids of any sort furnished by an individual (prostatic secretion for example) are injected into the tissues of the subject, much more disturbance is caused than if foreign albumin is injected. The practical bearing of this alleged discovery deals naturally with the entire subject of autogenous vaccines and the like. The brevity of the article and the newness of the subject, excuse the reviewer from dealing more extensively with this interesting topic.

Röntgen Diagnosis of Ulcus Ventriculi Callosum.—Faulhaber discusses the diagnosis of deeply extending ulcer of the stomach in a provisional communication. Not much advance has yet been made along these lines in comparison with the diagnosis of cancer of the stomach. The paper consists chiefly of case histories with *x*-ray photographs. In part the author merely avails himself of the fact that the ulcus callosum causes a constriction in the stomach (hour-glass stomach). The constriction appears smaller in a photograph than is actually the case. The constriction is detected by observation of the shape of the bismuth spot, as in general gastric diagnosis. According to the diagrams the recognition should be easy. The constricted portion or isthmus appears as a mere cord, although in reality it may be much larger. But not all hour-glass stomachs signify the presence of an active ulcer. The author estimates that the latter was present 10 times in 15. In the others, presumably, the ulcer had healed. Hence to demonstrate the presence of an active ulcer, other symptoms are necessary (hematemesis, melena, vomiting, etc. Moreover not all deep ulcers are so situated as to produce hour-glass stomach. The author, however, evidently does not intend to include the pyloric ulcer at all, for he ignores it. He states, moreover, that he does not include spasmodic or functional hour-glass stomach, although this may be due to a slight ulceration or erosion.

Sudden Deaths and the Parathyroids.—Grosser and Beike discuss this subject in a very concise monograph style. The subject of thymus death and the status lymphaticus in causing sudden death in the nursling and young child is a trite one. Persistent thymus, enlarged lymphnodes, or excessive lymphatic tissue have been freely discussed as causes, immediate or contributory to the fatality. But in the present paper, the parathyroids were accused of causing three deaths. The first child was 9 weeks old, and was suffering from pedatrophy. It was found dead and its death must have been very sudden. The parathyroids were doubled in size and showed evidence of hemorrhage. Thymus normal. The microscopic diagnosis was status lymphaticus, with death from parathyroid disease. The microscope showed these bodies to be extensively diseases but no attempt is made to explain the cause or nature. Two other cases were similar to preceding in course, termination, and autopsy findings, and a few others have been reported within the past two years. It is evi-

dently too soon to establish a distinct type of disease, owing to the smallness of material, the irregularity often in evidence of the syndrome, the possibility of other lethal elements, etc. But the claim for a "parathyroid death" appears at least as valid as that of deaths peculiar to the thymus or status lymphaticus. Some of these children were in a condition to succumb suddenly from slight causes, but the absence of the usual lesions in the lungs, heart, brain, etc., has made it necessary to seek the source of death in the only structures presenting lesions. But to explain how these lesions actually cause death has always been impossible. Take for example the author's third case, the intrathoracic organs were intact as they might have been in a healthy child suddenly killed by breaking its neck. The same may be said of the abdominal viscera and encephalon. Uric acid infarctions were present in the kidneys. Some of the viscera were hyperemic, while the gastric mucosa was anemic. But the sole organs to be actually affected were the parathyroids, which were the seat of the customary enlargement and hemorrhages.

Deutsche medizinische Wochenschrift.

September 29, October 6, 1910.

The Ehrlich-Hata Remedy in Malaria.—Werner has been nsing 606 largely in the Marine Hospital at Hamburg, and also, it would appear, on shipboard or elsewhere in the tropics. His own summary of his work is as follows: The drug is an efficacious antimalarial remedy much more powerful in ordinary tertian than in the tropical malaria (Brazilian). In the tertian form, after a single dose, combined intravenous and intramuscular, the parasite disappeared from the peripheral blood on an average within the first 24 hours. No relapse followed during an observation period of several weeks. In the tropical form the author succeeded in only one-half the cases in driving the parasite from the peripheral blood. But this result was only temporary, for the parasite along with the fever reappeared within a few days. The drug generally speaking is indicated where quinine fails or where there is quinine intolerance. The relative failure of 606 in Brazilian malaria has already been reported by Werner, and is explained *pro tem.* by the the theory that a different plasmodium is the cause of the latter.

Metabolism in Constitutional Obesity.—Locwy and Hirschfeld find that in normal individuals, in other words fat-poor subjects, the oxidative energy of their protoplasm is so low that it may serve as a minimum of metabolic action, standing on a par with the corresponding forces in individual obese subjects. It may in time be shown that certain of the latter may show higher rates of oxidation energy than those previously found. Values hitherto given do not represent anything pathological. It seems at present that certain oxidation values furnish merely a predisposing cause for obesity and that the minimum figures may occur in certain lean subjects. When such subjects do put on fat the condition is not a pathological one, but simply represents a surplus of intake over outgo, such as readily occurs from the choice of food, etc.

Prophylaxis of Typhoid Fever.—Zweig finds a number of clinical aspects of typhoid, as follows: 1. There is a type in which the fever is neither long nor high, but such cases do not give a better prognosis than others. 2. In other cases there is neither bacillary excretion nor Widal reaction up to the fifth week. 3. There are cases in which a Widal of 1:50-1:100 does not prove the existence of an acute typhoid. 4. In certain cases a perfectly normal appearing spleen may contain bacilli. 5. In bacillus carriers an extract of lactic bacilli should be used forthwith; and the same may be tried in acute typhoid. 6. Certain cases are contact cases. In any outbreak we must first think of such contact. We must always find out with whom the patient has taken his meals. 7. Each one of these table companions should have his temperature taken repeatedly. 8. In treating dirty patients woodwool is safer to use than moss.

Pneumatosis of the Stomach Cured by Bloodless Dilatation of the Cardia.—Fey refers to that rare condition, the sudden distention of the stomach by gas. It is of hysterical or neurasthenic origin in most cases, but in a few is dne to purely local causes. The mechanism consists of spasmodic simultaneous closure of the cardia and pylorus. A most desperate case (noted in the abstract columns of the MEDICAL RECORD at the time) reported by Schlesinger, recovered only after the establishment of a gastric fistula. The present author stretched the cardial orifice with a Gottstein sound, following the use of bougies of progressive size. The permanent distention secured a circumference of 14½ cm. All the ills due to cardiospasm subsided promptly and permanently. Patient still swallows air but readily expels it.

Difficulties in the Diagnosis of Progressive Muscular Dystrophy.—Erb gives four cases in detail, and then adduces the point that a typical affection of this sort does not exist. The entire development and course of the disease, its periods of quiescence and its relapses, and especially the restriction of certain phenomena to individual groups of muscles justify this conclusion. Thus we may find the electric excitability depressed in a number of muscles, with a localization and diffusion of the atrophy, but with immunity of the small hand muscles and actual hypertrophy of the infraspinatus. The matter of differentiation from spinal amyotrophy comes in question and this is not always easily made, for the two conditions have a number of symptoms in common. Another affection requiring differentiation at times is chronic anterior polyomyelitis. It may be conceded that when it comes to differentiating primary muscular dystrophies from spinal amyatrophies, we must admit the existence of transitional forms. These naturally present a great variety of symptoms of the most diverse character and are bilateral in character. Both conditions have at least been found to coexist at autopsy. If we assume that primary progressive dystrophy originates in the nerves of the muscles, the relationship between this affection and spinal amyotrophy does not appear so remote. Erb has always held to this belief. In recent days a connection between Thomsen's disease and amyotrophy has been claimed. The entire subject is as difficult as interesting to the specialist and more clinical reports are wanted.

Reflex Neuroses.—Killian writes briefly on this old theme. We see here one of the most progressive of scientific moderns discussing an old empirical subject. The author's conclusions are brief and pointed. There is a hypersensitiveness of the mucosa with special reference to agencies provoking the sensation of tickling. In subjects this constituted the most minimal irritation may cause local, regionary and even remote reflexes. Thus reflex neuroses are readily set up. The source of the reflex is all important as it then gives indications for treatment. Thus there are ethmoidal, sphenoidal and olfactory neuroses.

Centennial of the Berlin University.—All the papers in this number of the *Wochenschrift* save the two abstracted above, consist of addresses in connection with this centennial. These either do not lend themselves to abstracting or if reproduced would prove too long for abstracts. Thus Ribbert's paper on "Disease" is itself a condensation of the author's known views on this subject. The same is true of Haeckel's "Borderland of Science," and Wassermann's "The Influence of the Conception of Specificity on Modern Medicine." The balance of the articles are chiefly reminiscent.

Book Reviews.

Medical Vademecum in German and English. By B. Lewis, with preface by Prof. Dr. A. Politzer. Published by B. Lewis, Vienna. London: J. & A. Churchill. Leipzig and Stuttgart: K. F. Koehler. Philadelphia: P. Blakiston's Son & Co., 1910.

The novel idea of this work is one to be warmly welcomed by the medical profession of all German and English speaking lands, and its projectors are to be congratulated on the excellent method in which it is presented here. As stated in the preface, "The purpose of the work is to make as easily accessible as possible to German and English physicians the medical vocabulary of both languages." To this end the work is divided into three parts, with the German and its English equivalent opposite each other, line for line. Part I is devoted to original clinical pathological lectures by the younger men of the Viennese school. Part II is given up to histories, tests, examinations, operations, with instructions to patient and assistant. In Part III we find examinations by means of chemical and microscopical methods. It is needless to point out the ease with which an enormous number of German or English words could thus be mastered in a very brief time. Apart from its linguistic value this book shows the methods of teaching in vogue in the Viennese clinics, through the means of lectures by such men as Hirschl, Holzknecht, Kapsammer, Lorenz, Neuman, Schlesinger, Von Pirquet, and Wertheim. Great praise is due the editor for the care with which the work has been compiled and the pains which have been taken to make the English an accurate transcription of the German as well as perfect English. The book is convenient in shape and size, well printed on good paper, and reasonable in price, and we most heartily recommend it to members of the profession in this country as a valuable short cut to that difficult goal, good medical German.

Atlas und Grundriss der Zahnärztlichen Orthopædie. Von Zahnarzt Emil Herbst, D.D.S., in Bremen. Mit 3 vielfarbigen lithogr. Tafeln und 438 schwarzen, zum Teil zweifarbigen Abbildungen. München: J. F. Lehmann's Verlag, 1910.

Like all the atlases in this series of Lehmann's Herbst's work is brought out with a prodigality of illustrations that makes it most valuable and instructive. In fact, the illustrations are of equal importance with the text. The various apparatuses are shown and described in detail, as they are used for straightening the teeth and correcting deformities of the jaws. Two short chapters are devoted to operative work. It is always somewhat surprising to a physician to find to what a height the dental specialty has been carried.

Die Orthopädie des Praktischen Arztes. Von San.-Rat Dr. Georg Müller, Berlin. Mit 151 Textabbildungen. Berlin und Wein: Urban & Schwarzenberg, 1910.

Written ostensibly for the benefit of the general practitioner, this book contains little that can be of use to him. Instead of dealing with broad, general principles it is full of personal views of the author on what may be called minutiæ. One finds it difficult to believe that it was brought out in the year 1910. Its style is more that of ten or twenty years ago. Scoliosis is due to "certain predisposing causes." It is a matter of "heredity," and can often be cured by exercises. Müller lifts the vertebræ away from one another in Potts' disease in order that the tuberculous virus be not pressed out into the tissues by their crowding together. He regards the removal of the exudate from tuberculous knees as an essential of treatment, and in children. He strikes the bent knee to see if a tuberculous hip is well, and mobilizes his old tuberculous hips. He praises the Hessing braces, and then proclaims their impracticability in the hands of the general practitioner. Bilroth years ago said that the chief attribute of the Hessing brace was its great cost (horrendes Geld!), and that people who had nothing to pay a doctor could be persuaded to buy them. Hammer-toe is said to be due to short shoes, a view that has been abandoned, lo! these many years. That some of Müller's tuberculous hips recover in two or three months never makes him doubt his diagnosis, but instils in him the idea of "aborting" the disease. A book such as this should not be taken seriously. It reminds one of Chesterton's description of George Moore: "We feel as if we were being shown through a gallery of really fine pictures into each of which, by some useless and discordant convention, the artist had represented the same figure in the same attitude. 'The Grand Canal, with a Distant View of Mr. Moore,' 'Effect of Mr. Moore through a Scottish Mist,' 'Mr. Moore by Firelight,' 'Ruins of Mr. Moore, by Moonlight,' and so on, seems to be the endless series."

Appendicitis; When Should One Operate? By Julius Baumgärtner, Geheimer Medizinairat, ex-Directing Physician of the Hospital, Baden-Baden. With 32 illustrations. Translated from the Second German Edition by Amy M. Mander, formerly Member of the School Board for Wolverhampton, and revised by L. Martindale, M.D. London: T. Fisher Unwin, 1910.

This monograph of 64 pages is in the form of a lecture, and, written in a more or less popular style, is intended not only for physicians, but also for the laity. It contains some very good points and some poetry.

Hookworm Disease: Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis, and Treatment. By George Dock, A.M., M.D.; Professor of the Theory and Practice of Medicine, Medical Department Tulane University of Louisiana, New Orleans, and Charles C. Bass, M.D., Instructor of Clinical Microscopy and Clinical Medicine, Medical Department Tulane University of Louisiana, New Orleans. Fifty illustrations, including one colored plate. St. Louis: C. V. Mosby Company, 1910.

The present volume is one of those valuable monographs which appear only too seldom. The first chapter contains a brief history of the disease, and in it previous workers receive full recognition. The economic importance and geographic distribution are then discussed, and the former topic will be found to be of considerable practical value. Succeeding chapters treat of the zoologic features of hookworms, modes of infection, pathological anatomy and pathology, symptomatology, diagnosis, prognosis, prophylaxis, and treatment. The book is well written, and will be found indispensable to practitioners and those interested in hygiene and sanitation in those districts where hookworm disease is found. Further, it will prove an important factor in the solution of what is an economic problem in those same districts. The general getup of the volume is all that can be desired, and much more than is often obtained; it is admirably printed, with type of a size which makes the reading of the volume a pleasure.

Nephrocoloptosis. By H. W. Longyear, Professor of Gynecology and Abdominal Surgery, Detroit Post-graduate Medical School; Clinical Professor of Gynecology, Detroit College of Medicine; Gynecologist to Harper Hospital; Consulting Obstetrician to the Woman's Hospital; ex-President of the American Association of Obstetricians and Gynecologists. With eighty-eight special illustrations and a colored frontispiece. St. Louis: C. V. Mosby Company, 1910.

Dr. Longyear describes in this monograph the nephrocolic ligament, upon which he looks as the principal etiologic factor in nephroplosis. He gives in full the clinical symptoms of this frequent and serious condition, and names the various diseases with which it may be confused and the points in differential diagnosis. He recommends a special abdominal bandage in the treatment of the affection and describes an original operation for its radical cure. The book is lavishly illustrated, and is provided with a number of clinical histories which seem to bear out the author's theory of the causation of nephroptosis. Its perusal is recommended to both surgeons and physicians, who are so frequently confronted with the vexing problem of diagnosing and treating this affection.

Claims Arising from Results of Personal Injuries. The relation injury bears to disease and disease to injury. A treatise showing how personal injuries may affect various diseases, and how certain diseases may add to claims for accidents by protracting recovery. By W. Edward Magruder, M.D.; Associate Professor of Clinical Medicine, College of Physicians and Surgeons; Visiting Physician Mercy Hospital and Bay View Asylum; Medical Examiner and Adjuster for Life, Accident, Health, and Liability Insurance Companies, Baltimore, Md. New York and Chicago: The Spectator Company, 1910.

This is a small book forming a sort of compendium. It contains a brief compilation of opinions drawn from various medical writings on the subject of trauma in its relationship to about fifty different diseases. It is written in a popular style. The compiler states that it is for the use of all persons who may be engaged in the handling of claims arising from results of personal injuries, such as insurance companies, railroad claim adjusters, attorneys, and physicians. As a condensed reference book showing how personal injuries may affect various diseases, and how certain diseases may add to claims for accidents by protracting recovery, it will doubtless be found convenient. It contains also a useful bibliography.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Sixtieth Annual Meeting, Held at Pittsburg, October 3, 4, 5 and 6, 1910.

(Special Report to the MEDICAL RECORD.)

THEODORE B. APPEL, M. D., OF LANCASTER, PRESIDENT.

Tuesday, October 4—First Day.

President's Address.—Dr. THEODORE B. APPEL of Lancaster, Pa., in his address analyzing the purposes of the society as set forth in the ordinances found them to embrace a three-fold aim: Organization, individual aid, and duty to the public, uniting in the one definite object of advancement of the medical profession in its usefulness as a distinct entity in the body politic. The work of the committees on cancer, tuberculosis, for the prevention of trachoma and the abuse of privileges by the refracting opticians, showed the progress of work for the public. In the matter of legislation the hope to unite all national efforts in the fight against disease had come to be nearly realized. The record of the sixty-two years of the society's life was a matter of medical history. Future problems were necessarily to be settled by the cooperation of organized bodies with the people.

Some Considerations on Infant Mortality.—Dr. SAMUEL G. DIXON of Harrisburg divided influences responsible for excessive infant mortality into: (1) Prenatal, and (2) postnatal, and claimed that preventive measures must be educational and discretely philanthropic. The problem was defined as concerning the mental, moral and physical prosperity of all people throughout the civilized world, and to that extent there should be enlisted the influence of individuals, societies, churches, schools, states, and nations. This offered the only solution of the large problem.

Typhoid Fever in Pennsylvania—Past, Present and Future.—Dr. SAMUEL G. DIXON and Dr. B. FRANKLIN ROYER of Harrisburg presented this paper which was read by Dr. Royer. Typhoid fever was said to be a preventable disease by prophylaxis and sanitation. The work done by the Department of Health was reviewed, and the possibilities of the future outlined. Such advance, however, was possible of accomplishment only through hard work, an outlay of much money, and close cooperation between the family doctor and the health official.

Work of the Council on Pharmacy and Chemistry.—Dr. DAVID L. EDSALL of Philadelphia summarized the problems which had been met by the Council and referred to the support received from the medical profession and some manufacturers, speaking also of obstructions offered by other manufacturers. He reviewed the work accomplished, speaking of its value to the profession, and directed attention to future problems.

Wednesday, October 5—Second Day.

A Report on the Tuberculosis Situation in Pennsylvania for the Year 1909.—J. BYRON DEACON, Executive Secretary, Pennsylvania Society for the Prevention of Tuberculosis, Philadelphia, considered the extent of tuberculosis in Pennsylvania in 1909, the State's antituberculosis equipment at the beginning of that year, and the increase in equipment during 1909. He then compared Pennsylvania's work in 1909 with the work of previous years and with the work of other States.

Mr. ALEXANDER M. WILSON, Director of the Sociological Department of the Henry Phipps Institute, Philadelphia, said that the dispensary should be the center of the campaign against tuberculosis. Mr. Wilson emphasized the importance of a coordinated plan in combating tuberculosis, and said that another important feature was the hospital for advanced cases. What were needed in every county were hospitals free from the stigma of pauperism.

Mr. EDGAR M. GREEN, Easton, said that it was too early to say how much work had been accomplished by this antituberculosis movement, as the statistics dated back only to 1906. He did not believe it right to force advanced consumptives to go so far away from home that they could not at frequent intervals see their families and friends. Therefore, hospitals for advanced cases should be established in every county or in every district comprising three or four counties.

Dr. LAWRENCE F. FLICK, Philadelphia, thought that the crusade could be better carried on by private organizations than by the government; that work properly done brought a reduction in the death rate from tuberculosis; that local organization and local control of tuberculosis gave the best results for the least money; that care of advanced consumptives in hospital beds near their own homes was our best asset for the prevention of tuberculosis; and that the interest of the people at large could be most easily aroused by getting them to participate in the actual work.

The Early Diagnosis of Pulmonary Tuberculosis.—Dr. ALFRED STENGEL, Philadelphia, said that there were a large number of cases of tuberculosis that began clinically in ways other than with colds or coughs, and mentioned the following modes of onset: The pneumonic cases; the bronchitic cases; those which begin with obscure fever, chill, and other symptoms of infection, but without definite localization; those that begin with no very manifest symptoms, but with indication of failure of health and vitality; hemorrhagic cases; and pleurisy cases. No man, he said, could diagnose pulmonary tuberculosis at a stage when it should be diagnosed by making an examination through the clothes. Regarding the specific reaction, he considered this another direction in which the practitioner allowed himself to be too much influenced by the laboratory. He did not think heredity of much importance, but said that environment could not be emphasized too much.

Dr. H. R. M. LANDIS, Philadelphia, Director of the Clinical Department of the Henry Phipps Institute, said that every case that presented itself should receive a thorough physical examination. Occupation might give a clew to the condition. Typhoid fever and pneumonia, he thought the greatest sources of error in the diagnosis of tuberculosis. Any individual who had a pulmonary hemorrhage should be labeled as a case of pulmonary tuberculosis. Pleurisy was usually a forerunner of a pulmonary outbreak. If persons with chlorosis were put on the regimen prescribed for tuberculosis, the condition often cleared up amazingly soon.

Dr. GEO. W. NORRIS, Philadelphia, said that the examination of a case would take from twenty minutes to an hour. All doubtful cases should be treated on the supposition that tuberculosis exists. He felt that the diagnosis could be made by the old-fashioned method, without resort to the modern laboratory devices, in a very large proportion of the cases.

Dr. CHARLES H. MINER, Wilkes-Barre, said that the Committee on Tuberculosis appointed by the Society thought that it would be of interest to have one meeting of each county society devoted to a clinic on tuberculosis, and that a number of such meetings had been held.

Dr. WILLIAM C. WHITE, Pittsburg, said that if patients were questioned about having a little morning sputum, one would find out that this was present in a large percentage of cases. He considered this as a factor in producing progression in the disease.

Dr. LAWRENCE F. FLICK, Philadelphia, said that in every examination made the healthy tissue should be included. The two things most frequently overlooked were empyema and old lesions that had recovered far enough to permit of their giving but very few signs. Dr. Flick thought that

Dr. Stengel had been too severe in saying that no living man could examine a patient over the clothing.

Dr. Arthur A. Watkins, St. Benedict, Cambria County, felt sorry that Dr. Flick had made the remark that he had in regard to examination over the clothing; as he was afraid that many physicians were getting to be satisfied with making an examination in this way, and that this would be an additional excuse for them to do so.

Dr. Stengel said that Dr. Flick had misrepresented him in stating that he had said that no patient could be examined through his clothing. What he had said was that no man living could diagnose tuberculosis properly without taking the patient's clothes off.

The Open-Air School.—Dr. William C. White of Pittsburg said that Pittsburg had probably the largest school of this kind in the United States. The question of the open-air school involved a care of every child who is later to be one of the citizens of our country. It also involved the building of proper school buildings in the State, and the proper medical supervision of the children by the most intelligent physician that could be obtained.

Dr. K. H. Van Norman, Pittsburg, said that the children in these open-air schools were not treated as dispensary cases, but as hospital cases. He thought that people interested in such schools did not pay enough attention to the feeding of the children, while at the hospital they were fed from a medical standpoint. After having gained five or six pounds in weight they were very much keener at their work.

Dr. John B. McAlister, Harrisburg, thought that the question of the open-air school was very largely a business proposition. The State appropriated very large sums of money for education, and had the right to expect the very best results. In judiciously selected cases, the open-air treatment had been very successful.

Dr. H. H. Herbst, Allentown, said that he had been connected with the public schools for twenty years, and that from his observation he could say that the open-air school was needed. The first question to be settled was that of whom to place in these schools.

Dr. Clark of Pittsburg thought that very little tuberculosis originated in the school, the great trouble being in the homes, even in the good ones.

Thursday, October 6—Third Day.

Venereal Affections Considered as Epidemic Diseases.—Dr. J. F. Schamberg of Philadelphia read this paper, saying that there was a lamentable lack of interest in Pennsylvania as to the spread of venereal diseases. A statute should be enacted requiring a physician's certificate as to the physical eligibility of males for marriage. The world movement on foot for the prophylaxis of venereal diseases and the attitude of physicians to it as well as that of the laity puts the matter in a hopeful position.

Prophylaxis of Venereal Diseases.—Surgeon M. F. Gates, U.S.N., read this paper saying that this subject was of great importance to the military service owing to the inroads made by venereal diseases upon the fighting efficiency of the forces of the nation. It was possible to obtain statistics as to morbidity of these diseases more accurately in military than in civil life because sailors and soldiers were required to submit to examination. During recent years much more interest was taken in prophylaxis and measures were being carried out which would have received scant attention a few years ago.

Dr. L. F. Flick of Philadelphia said that it was impossible to control the disease and prevent new infection without registration of venereal diseases. There should also be required for a marriage license a certificate of freedom from venereal diseases from a reputable physician. Every hospital in the commonwealth should be thrown open to the treatment of venereal diseases.

Hon. William A. Magee, Mayor of Pittsburg, said that the law did not authorize a public official to say that prostitution should be regulated; that prostitutes should be dispersed all over the city or that prostitution should be permitted to exist in one form or another. The police power merely attempted to act in regard to this thing in accordance with what they believed the fickle popular fancy of the moment to be. If the police did their duty they would have to arrest several thousand persons every night, but the public really did not want them arrested. The public did not intend that the laws which are now on the statute books should be enforced. The hospitals of the State should be opened up for the treatment of venereal diseases. This could easily be done if the Legislature demanded it.

Dr. D. G. McCaskey of Witmer said that as he had observed there were no laws regarding prostitution in Japan but that it was there regulated by the commercial element as their interests demanded. The prostitutes were segregated and once each week were required to submit to the most thorough clinical and microscopic examination. Those found infected were treated in hospitals until they had recovered.

Dr. J. A. Nydegger of Pittsburg, of the U. S. M. H. S., believed that the only means of eradicating or lessening venereal diseases was by public education. He believed that this education should be begun in the home and the school and then carried on to the older people.

Some Barriers to Progress in the Case of the Insane.—Dr. W. K. Walker of Pittsburg read this paper saying that mismanagement and abuses in various insane hospitals in the State constituted serious barriers to progress in the care of the insane. He advocated that a commission be organized to investigate all the details of the various insane asylums with a view to procuring adequate legislation to remedy these evils.

The Necessity of a State Laboratory of Pathology for the Study of Insanity.—Dr. T. H. Weisenburg of Philadelphia read this paper saying that further knowledge of insanity could be gained only through pathological work. Every physician connected with an insane hospital should have a working knowledge of the pathology of insanity and of the progress that was being constantly made in serum therapy. A State laboratory was therefore necessary.

State and County Care of the Indigent Insane.—Dr. C. W. Burr of Philadelphia read this paper saying that Pennsylvania, while theoretically assuming the care of its insane, did not supply sufficient provision for them. Certain of the counties took fairly good care of the insane, others did not. It was better to have one central body, officials of the State, to take charge of all indigent insane than to have many county officials responsible only to the county authorities.

Dr. C. K. Mills of Philadelphia said that we had methods which were not so bad if these methods could be carried out under the provision of the statutes. The State Board of Charities and the Committee on Lunacy had certain powers but it had been found that they had not been able to do all that was imperatively required.

Dr. T. M. T. McKennan of Pittsburg said that a committee had been appointed by the State Legislature to investigate the condition of affairs in the State of Pennsylvania as regards the care of the insane and that the Commission had gone to the different hospitals in the State and investigated them. They reported to the Legislature of 1902-03. From their report was formulated a bill which was modeled after the New York State law but that bill was finally put into committee and never brought out for certain reasons. A movement in that direction was all that was required at this time to get a law passed.

Dr. E. E. Mayer of Pittsburg said that the same care in

nursing, recording of symptoms, and treatment was necessary in county and State asylums as in general hospitals and the medical profession must insist on this. Psychopathic hospitals should be created for the observation and treatment of patients before commitment. Recreation grounds and workshops should be compulsory adjuncts of every institution to which the insane were committed.

Dr. W. W. Hawke of Warren said that in his ten years' experience in the Philadelphia Hospital for the Insane there had been a number of attendants arrested, not only for slight evidences of brutality but even for murder, and none had ever yet been convicted.

Dr. Theodore Diller of Pittsburg said that he favored a central Board of Lunacy with larger powers than was at present possessed by the Lunacy Committee. He now favored the view that the State should take care of all of her insane.

Officers.—The following officers were elected to serve for the ensuing year: *President*, Dr. John B. Donaldson of Canonsburg; *Secretary*, Dr. C. L. Stevens of Athens; *Assistant Secretary*, Dr. Alexander R. Craig of Philadelphia; *Treasurer*, Dr. George W. Wagoner of Johnstown.

Harrisburg was named as the place of the next meeting.

The House of Delegates passed without a dissenting voice a resolution offered by Dr. John B. Roberts, requesting the Legislature to appoint a commission consisting of members of the House of Representatives, the Senate, the State Board of Public Charities, two physicians and a lawyer, to investigate the subject of State appropriations to hospitals not under State control, and the management of all hospitals, and to report upon a better method than the present of making hospital appropriations. The House reaffirmed its position taken last year upon the question of pure foods, endorsing the work of the Federal authorities on this subject. It endorsed also the principles outlined in the Owen Bill, providing for the establishment of a National Department of Health. Commissions were authorized to continue the study of malignant growths, the end results in the treatment of fractures of the femur, and the work concerning trachoma.

SECTION ON MEDICINE.

Tuesday, October 4—First Day.

Oration on Medicine. Recent Progress in Medical Sociology.—Dr. Charles H. Miner of Wilkes-Barre thought the medical profession in this country had probably done more for the benefit of the people and for their own reputation in the past few years through sociology than in any other field of their labor. He referred to work in the campaign against tuberculosis, in the medical inspection of schools, the temperance movement, and in the prevention of cancer and venereal diseases. The great possibilities of social service in connection with hospitals was mentioned and consideration given to the interest taken by the medical profession in industrial insurance, the employers' liability law, prevention of infant mortality, and a clean milk supply.

Gall-Bladder Dyspepsia.—Dr. John A. Lichty of Pittsburg detailed the symptoms of gall-bladder dyspepsia, and the conditions included in gall bladder and duct affections. Symptoms usually described as indicating cholelithiasis were said to be found in only 5 to 35 per cent. of all cases; hyperchlorhydria in about 70 per cent. of 208 cases of gall bladder and duct affections. From experiments on dogs it seemed that hyperchlorhydria was secondary to affections of the gall bladder and ducts and was a symptom of considerable value. In cases of hyperchlorhydria where gastric and duodenal ulcer were excluded, before the diagnosis of nervous dyspepsia was made, the presence of disease of the gall bladder should be carefully considered.

The Treatment of Fermentative and Putrefactive States of the Intestines.—Dr. David L. Edsall of Philadelphia emphasized the fact that in this class of cases attention was too often directed to the bowel to the exclusion of the stomach. The very great importance of the routine examination of the feces was mentioned. Test diets he thought were often misleading, and a better plan was to have examinations made during the usual diet. Improvement of the general tone of the abdominal muscles, attention to the circulation, and to the blood pressure were regarded as important factors in treatment, with efforts directed toward an increased resistance. Long continued use of active purgatives was decried. Surgical intervention was believed to be sometimes indicated.

Gastric Manifestations of Nongastric Disease.—Dr. Clement R. Jones of Pittsburg discussed the symptom complex of nongastric disease as compared with those of true gastric origin.

Constipation of Colonic Origin.—Dr. Judson Daland of Philadelphia said that cases of chronic constipation due to abolition of the rectal reflex might be relieved by a determined effort of the patient to secure a movement of the bowels each morning immediately after breakfast. Such effort might with advantage be supplemented by the introduction of a soluble glycerine suppository, or the employment of an enema. Diet, exercise, drugs, surgery, and other remedial agents were spoken of in detail as of value.

Dr. I. J. Moyer of Pittsburg thought it probable that many cases of beginning gall-bladder disease were due to modern habits of eating and of nervous hurry. He agreed with Dr. Edsall that the cause of many gastrointestinal conditions was outside of the intestine. The management of these cases he thought had come into disrepute from having treated them entirely symptomatically.

Dr. Ernest LaPlace of Philadelphia emphasized the importance of looking elsewhere for the cause of the trouble if not located in the organ apparently the seat of the difficulty. He felt there was a tendency to forget the intimate relation of all the organs within the abdominal cavity.

Dr. James M. Anders of Philadelphia agreed that gallstone dyspepsia was frequently overlooked even by competent observers. An anatomical basis outside of the organ implicated should be suspected in the presence of symptoms not yielding to ordinary measures.

Dr. Lichty, in closing, explained that the object of his paper was to counterbalance the paper by Mr. Moynihan laying considerable stress upon appendix dyspepsis. Much that was said of appendix dyspepsis he felt was true of gall-bladder dyspepsia.

Dr. Daland, in closing, said that the possible objection to frequent rectal irrigation could be overcome by careful determination of the quantity, time, and temperature of the injection.

The Significance of Transient Cerebral Crises and Seizures as Occurring in Arteriosclerotics.—Dr. James D. Heard of Pittsburg considered as some of the possible factors in cerebral crises: The action of a toxin upon brain cells in localized areas; a spasmodic localized contraction of cerebral arteries sufficient to interfere with the function, but not to affect the integrity of a part; so considerable a decrease in a compensatory hypertension that certain areas of the brain are temporarily insufficiently supplied with blood through the sclerotic vessels supplying them; localized areas of edema in the brain substance. In the light of present knowledge, a toxic basis might be assumed as a general underlying cause for all these conditions. The supposition that the condition was due to a localized poisoning of brain cells was said to be that which Tanzi invokes to explain the closely allied, if not at times identical, seizures of progressive paralysis. An intermittent closure of the blood vessels supplying the affected

area was mentioned as a simpler possible factor, which theory has the adherence of Russell, Osler, and others. Evidence as to separate vasomotor control over the cerebral vessels was considered, and the conclusion reached that the probability was strongly in favor of the fact that these vessels do contract or dilate independently of the action of the center in the medulla. Reference was made to the association of cerebral seizures of an apoplectiform nature with migraine, and to the fact that J. Mitchell Clark had observed apoplectiform seizures in nine members in three generations of a migrainous family in which hemiplegia, usually accompanied with aphasia, was a constant feature. The importance of an appreciation of the nature of these crises was said to rest upon the fact that their proper interpretation might influence both prognosis and treatment. The danger was pointed out of having a routine conception as to the blood pressure desirable in an individual of a given age. As the cerebral seizures are usually the result of toxic influences it was pointed out that prompt measures should be instituted aiming at the removal of circulating poisons and the limitation of their further production.

Dr. Theodore Diller of Pittsburg had seen several cases such as referred to by Dr. Heard and appreciated the difficulty in determining the etiology. In an apoplectic stroke in a man in the forties the practitioner should bear in mind the possibility of paresis. In this connection the mental condition of the patient and a history of previous attacks were to be considered.

Clinical Studies in the Auscultatory Method of Determining Blood Pressure.—Dr. Edward H. Goodman and Dr. A. Alexander Howell of Philadelphia contributed this paper which was read by Dr. Goodman. The belief was expressed that by studying the relation of the five phases to one another much could be learned diagnostically from the auscultatory method. No particular phase was regarded as of greatest significance, but the importance of each phase was to be interpreted by its relation to the other phases and by its relation to the total pulse pressure. The length of the individual phase should be recorded and its percentage relation to the pulse pressure ascertained. The following conclusions were drawn: (1) That for accuracy and simplicity, the auscultatory method of estimating blood pressure is to be preferred to any clinical method. (2) In diagnosing aortic insufficiency, absence of the fifth phase is almost pathognomonic. (3) In the diagnosis of cardiac neuroses, the recognition of tonal arrhythmias and irregularities in maximal and minimal pressure, and variation in sequence relation will prove of much value.

The following papers were read by title:

High Arterial Tension. A Clinical and Therapeutic Study.—Dr. R. Max Goepp of Philadelphia.

Medical Treatment of Ulcer of the Stomach.—By Dr. James B. Walker of Philadelphia.

Dysuria Due to Hyperacidity of the Urine.—By Dr. Henry D. Jump of Philadelphia.

Wednesday, October 5—Second Day.

Some Observations on Mitral Stenosis.—Dr. James C. Wilson of Philadelphia referred to the general agreement that rheumatic endocarditis is the most common cause of mitral stenosis, and to the probability that whooping cough is the occasional cause of the primary endocarditis as a result of the great mechanical stress upon the mitral valve in the paroxysm. That mitral stenosis carries with it some degree of immunity against pulmonary tuberculosis he felt required confirmation. The etiological uncertainties were to his mind greatly increased by the numerous cases encountered in young women in which none of the ordinary causes of endocarditis could be determined. Muscular or spasmodic mitral stenosis; and the mitral stenosis of acute malignant endocarditis were also mentioned under causation. The well recognized types of anatomical lesions in mitral stenosis showed variations so essentially different in their circulatory effects as to constitute at least two valvular diseases having little else in common than a narrowing of the auriculoventricular orifice, the physical signs to which that narrowing gives rise, and a tendency to the transference of the blood pressure from the arterial to the venous side of the circulation. In Dr. Wilson's experience, hemoptysis in mitral stenosis, though often very alarming, had been usually followed by abatement of cardiac symptoms and sometimes by prolonged improvement. Prognosis was regarded as less favorable than in mitral insufficiency. Treatment was to be carefully adjusted to the individual case.

Treatment of Cardiac Irregularities.—Dr. Alfred Stengel of Philadelphia following the more common classification divided cardiac irregularities into three important types, viz.: Juvenile; extrasystolic; nodal rhythm. Conditions ultimately determining myocardial failure were noted as (*a*) progressive increase of the myocardial disease; (*b*) conditions outside the heart, finally causing incompetency. Treatment designed to prevent the former condition included improvement in nutrition, regulated exercise, tonic treatment, antisyphilitic treatment; that to prevent overhardening of a damaged myocardium, correction of gastrointestinal troubles, relief of strain and undue blood pressure, promotion of renal and dermal activity. The fact was emphasized that in very many cases of beginning failure of cardiac power attention should be directed to the gastrointestinal tract, and to external conditions.

Blood Pressure and Other Observations in Hypertrophy and Dilatation of the Heart.—Dr. Joseph H. Barrach of Pittsburg based his observations upon a study of a series of over 50 young men who had practised distance running for at least six months. The pure forms of hypertrophy and dilatation such as occur in the absence of valvular lesions and history of previous disease were mainly dealt with and the author concluded that there is a usual occurrence of transitory dilatation following cardiac overstrain.

The So-called Nodal Rhythm of Mackenzie.—Dr. Joseph Sailer of Philadelphia observed that Mackenzie and others had found as an essential feature of the tracing of the venous pulse a wave which occurs before the time of the contraction of the ventricles, which had been pretty definitely ascertained to be due to the contraction of the auricles, forcing the blood back into the veins of the neck from which the tracing is taken. Mackenzie had observed in many of his cases of persistent arrhythmia that this wave was lacking. He therefore concluded that there was a synchronous contraction or a paralysis of the right auricle. In trying to find the cause of this it occurred to him that the node of Tawara, which is found on the wall of the right ventricle and is probably situated upon the conduction fibers passing to the bundle of His, might be involved, and that its involvement would account for this condition. The electrocardiograph had shown that a series of fine contractions due to muscular effort take place in the right auricle between the ventricular contraction, so that complete paralysis of the auricular wall cannot be present. This, however, did not necessarily invalidate Mackenzie's explanation. Mackenzie had applied the term "nodal rhythm" to this condition because he believes that the lesion is situated in the node. This view Dr. Sailer said had not met universal acceptance.

Dr. Lawrence Litchfield of Pittsburg emphasized the statement regarding the frequency with which mitral stenosis is overlooked. Too often after making the diagnosis of mitral insufficiency the examination of the heart is discontinued and thus the stenosis overlooked. He spoke of the possibility of nitroglycerine doing much damage.

Dr. George W. Norris of Philadelphia admitted that nitroglycerine, under some circumstances, was a good drug, but believed its use was abused. As a rule also the drug was not correctly given.

Dr. James D. Heard of Pittsburg spoke of the value, in the early stages of the condition, of measures other than drugs.

Dr. Stengel, in closing, referred to the relationship between polycythemia and cardiac disease, and to the importance of the temperature of the saline bath.

Dr. Sailer, in closing, spoke of the interest attaching to nodal rhythm chiefly because of its introducing a further refinement in cardiac diagnosis. Treatment was regarded as largely in the experimental stage and apt to be directed according to the individual choice of the physician.

Remarks on the Treatment of Croupous Pneumonia.—Dr. George W. Norris of Philadelphia regarded many of the drugs employed in the treatment of pneumonia as worse than useless. Serum treatment had proved of no value as had also that with leucocytic extracts. Vaccine therapy he thought somewhat promising. He emphasized the fact that death in pneumonia was generally the result of toxemia and to a considerable extent independent of pulmonary involvement. In its production vasomotor failure was said to play a much more prominent part than heart failure. Treatment was often misdirected and inefficient because this fact was not sufficiently appreciated. All drugs and methods tending to lower blood pressure were, therefore, contraindicated.

The Public and Private Aspects of the Pneumonia Question.—Dr. William Charles White of Pittsburg suggested in this paper two plans for a systematic crusade against pneumonia: (1) The discovery of a specific cure: (2) The inauguration of a popular campaign of education and instruction in the laws governing the prevention and cure of pneumonia similar to, and involving the same scope as the plan already utilized for the reduction of the mortality of tuberculosis.

A Case of Progressive Universal Pneumonia with Recovery, Presenting Some Very Unusual Features.—Dr. William H. Mercur of Pittsburg described a case marked by rapidity of involvement, absence of cyanosis, of toxic symptoms, of marked delirium, and of excessively high pulse rate, long continued, and excessively high rate of respiration. The possibility of an underlying tubercular infection was considered and treatment outlined.

Dr. Frank D. Stolzenbach of Pittsburg had seen Dr. Mercur's case with him. The only case he had found in the literature was reported in the *British Medical Journal* for July 24, 1909, that of a child 3½ years of age in whom the affection had spread from the lower lobe of the right lung, involved the middle lobe and then the lower lobe of the left lung. The temperature dropped to normal, and within a week the left base was involved and later on the left upper lobe.

Dr. Edgar M. Green of Easton agreed that after the extent of the disease has been determined it was much more important to pay attention to the abdomen than to the chest.

Dr. Lawrence F. Flick of Philadelphia regarded the increase of average life and the decrease in tuberculosis as a possible explanation of the increased prevalence of pneumonia. In his experience, pneumonia was one of the most frequent avenues of exit from life of tuberculous subjects.

Dr. James D. McClure of Wilkinsburg regarded the most important factor in the treatment of pneumonia the rendering of the patient comfortable until the disease had run its course. He advised against the giving of an opiate since the patient was already full of poison. The tympanitic condition of the bowels was uncalled for and he believed it to be due to feeding during the paralyzed condition of the secreting organs. Treatment should be largely eliminative.

Dr. I. J. Moyer of Pittsburg would use morphia in pneumonia only for pain and restlessness in 1/16 gr. doses repeated every two hours until the effect is attained.

Dr. John W. Boyce of Pittsburg believed that the routine administration of strychnia in pneumonia was harmful. He marveled upon the impression received by the average graduate that strychnia was the universal remedy to administer, and felt it important that they be taught that strychnia could kill without ever producing a muscular twitch.

Dr. Clement R. Jones of Pittsburg regarded salol in five grain doses every hour almost a specific in the treatment of pneumonia.

Dr. Arthur Allan Watkins of St. Benedict thought that if every physician could have an attack of pneumonia it would alter his views as to treatment. Personally he had found morphia, and an abundance of fresh air particularly grateful.

Dr. Mercur in closing said he did not use morphia if possible to avoid it, because of its hindrance to elimination. He thought it better to feed patients moderately and to watch against tympanites. Medication was a minor matter.

The Effect of the Different Forms of the Leucocytes in Cases of Tuberculosis Produced by Some Therapeutic Measures.—Dr. Myer Solis-Cohen and Dr. Albert Strickler of Philadelphia presented this paper which was read by Dr. Cohen. One hundred and thirty-five leucocyte counts had been made on 25 patients with pulmonary tuberculosis. The effect of various physiological measures and of medicinal measures was given in detail.

Enuresis from Thyroid Insufficiency.—Dr. E. Bosworth McCready of Pittsburg presented this paper, stating that there is a large class of individuals, including those who as children showed various developmental defects, whose condition might be traced to a primary defect in the ovum. He believed that the resulting cell hypoplasia involved the structural elements of the ductless glands. He regarded enuresis as a very common symptom of hypoplasia, and believed that the administration of thyroid extract would not only relieve the enuresis but that it also caused a very marked improvement in the general physical and mental condition.

Dr. Joseph Walsh of Philadelphia presented "Treatment of Hemorrhages in Tuberculosis of the Lungs," which paper was read by title.

Thursday, October 6—Third Day.

Mental Disturbances Following Traumatism; Medico-legal Considerations.—Dr. Alfred Gordon of Philadelphia had studied 37 cases during a period of eight years. Among his conclusions were noted: That trauma may be a determining cause of abnormal psychic manifestations, following immediately, or some time later; that their appearance weeks after the shock excites suspicion of their existence in a mild form immediately following the accident. Confusional states and delirium he had found to be the most frequent forms of insanity following traumatism. Dementia was mentioned as the possible ultimate result of persistent confusional and delirious states. Traumatic psychoses were said not to present a strictly defined morbid picture, but presented a great variety of psychic manifestations.

The Present Status of Psychotherapy.—Dr. E. E. Mayer of Pittsburg spoke upon this subject, presenting some of the practical principles he thought should be remembered by the general practitioner. He advised an intimate knowledge of the patient's mental complexus ascertaining what things are troubling him. The treatment of these conditions was said to have a technique fully as important and as complex as that of any other disease.

Traumatic Neurosis.—Dr. J. L. Salinger of Philadelphia said that while the causative factor in traumatic neurosis is trauma, there were many predisposing conditions. The litigation frequently ensuing after accidents was regarded as a large etiologic factor. If proper and speedy adjustment of the patient's claims was impossible, he believed the neurosis was apt to be prolonged.

Dr. Theodore Diller of Pittsburg said that while the claims of the subjects of traumatic neurosis remained unsettled there was practically no effectual treatment. He would hesitate to attempt an analysis of the patient's mental troubles as suggested by Dr. Mayer, though he had practised the old-fashioned psychotherapy, that of ordinary sympathy, re-education, suggestion, etc.

Dr. Tom A. Williams of Washington, D. C., thought the general practitioner should at once disabuse his mind of there being any special difficulty or special complexity in psychotherapy. Psychoanalysis he claimed was no more difficult or impossible than chemical analysis, but required a technique of its own and a great deal of knowledge of the phenomena, which knowledge, however, might be acquired by any one willing to take the trouble.

Dr. Gordon in closing said there was no rule in regard to recovery in cases of litigation following traumatic neurosis, and instanced cases in which the neurosis had remained in spite of satisfactory settlement of litigation. Also he had had cases with no expectation of indemnity in which the neurosis had continued.

Dr. Mayer in closing said it was the physician's duty to find the cause of trouble—physical, or mental, and doubted not that Dr. Diller did this, though possibly not dignifying his effort by calling it psychotherapy.

Dr. Salinger in closing expressed his belief that the cases mentioned by Dr. Gordon as not recovering, although receiving indemnity, were not cases of neurosis, but of organic disease.

The Symptomatology and Pathology of Tumors of the Pituitary Body; Pathological Report of One Case.—Dr. J. H. W. Rhein of Philadelphia reported this case in a man of 33 years with symptoms extending over two and one-half years. Autopsy revealed a large tumor in the region of the hypophysis, which proved microscopically to be an adenocarcinoma.

A Case of Brain Abscess with Post-Mortem Findings; Presentation of Specimen.—Dr. Theodore Diller and Dr. James K. Everhart of Pittsburg presented this paper. Improvement followed operation but there was return of symptoms. The wound was opened, but because of a general convulsion while on the table operation was delayed. The patient afterward died suddenly and autopsy revealed a large abscess entirely within the brain substance and apparently not communicating with the first abscess cavity which was just below the dura mater. Dr. Diller felt that he had made a mistake in not having continued the operation.

Dr. Tom A. Williams of Washington felt that surgeons and neurologists were too timid about operating on the brain, for it had been most conclusively demonstrated that the brain can be operated upon with as much impunity as the abdomen.

Some Observations Upon the Treatment of Alcoholic and Other Drug Addictions.—Dr. C. C. Whaley of Pittsburg in this paper said that drug addiction presented its own peculiar etiology and that it is as distinctive a specialty as is neurology. As to cure it separated itself into three classes: (1) Those who began the use of the drug inadvertently, and who after a short course of treatment remained free from the habit; (2) Degenerates, those who take their drugs as a dissipation, and who are incurable; (3) Those who, owing to reduced resistance by long use of the drug, find cure a slow and tedious process.

Dr. Diller believed that religion offered the best remedy in drug addictions, that if it were possible to get a dose of the real article into the patient it was the best and the most fundamental source of help. He claimed this as a result of his own observations supplemented by the testimony of some of the most conservative men.

Progress in Empirical Therapeutics.—Dr. John W. Boyce of Pittsburg suggested the possibilities of progress were the observation of drug effects as carefully recorded as were inoculation experiments in the laboratory, if the value of "controls" were appreciated; also as much thought would be devoted to the compounding of the prescription as the surgeon gave to the preparation of gauze and suture, and it would be fully realized that the whole business of a physician would be to cure disease, appreciating at the same time that to this end no means compared with the skillful handling of drugs.

The Diagnosis and Treatment of Relaxed and Weak Feet.—Dr. Charles A. E. Codman of Philadelphia said that the relaxed foot and the weak foot commonly referred to as flatfoot was, technically speaking, a relaxed or weakened condition of the plantar arch. The author's method and the exercises for permanent relief were described.

Dr. Rugh agreed with the author upon the importance of the exercise for the correction of the condition. In diagnosis care should be taken not to accept the history of "rheumatism."

The Treatment of Acne Vulgarus.—Dr. John G. Burke of Pittsburg advised the usual constitutional measures in the treatment of acne. An additional constitutional agent was found in bacterins, though the results could not be relied upon to the exclusion of other remedies Stock vaccines had been of little service. He had found the following preparation of service: Beta-napthol, 5; precipitated sulphur, 20; green soap, 35; lanoline, 35. Although the *x*-rays would cure, the tendency to produce telangiectasis made one hesitate to employ them.

The Diagnosis of Hay-Fever in Children.—Dr. William C. Hollopeter of Philadelphia claimed that hay-fever is essentially a disorder of early life. The sequelæ of this affection, annually repeated, was that which was found eventually seriously handicapping mature life in the form of asthma, emphysema, cardiac and renal troubles. Like diphtheria, hay-fever was a local expression of a systemic toxemia, and its relief ofttimes called for the making over of the child physically as well as mentally.

Officers of the Section on Medicine elected for the ensuing year: *Chairman*, Dr. Edgar M. Green of Easton: *Secretary*, Dr. Charles H. Miner of Wilkes-Barre.

SURGICAL SECTION.

Tuesday, October 4—First Day.

The Chairman, Dr. Edward Martin of Philadelphia called the meeting to order in the main auditorium of the G. A. R. Memorial Hall, Pittsburg, at 2:05 p. m.

Subacromial Bursitis; Its Etiology, Anatomy, and Pathology.—Dr. Americus R. Allen of Carlisle read this paper, saying that sepsis, traumatism, and non-use are the causes of subacromial bursitis. The abnormal conditions found in these cases are thickening of the bursal walls, adhesions, and adhesive bands. In some cases cheesy deposits occur.

Treatment of Subdeltoid Bursitis.—Dr. J. T. Rugh of Philadelphia presented this paper saying that inasmuch as the seat of the trouble was in close relation to the shoulder joint, the restoration of function would be accompanied by pain. The fact that treatment would extend over a prolonged period of time must be impressed upon the patient and his will power and fortitude must be developed to secure and maintain the thorough coopera-

tion so essential to success. Many of these patients were unfortunately of the nervous, shrinking and pessimistic type, which rendered the labor and efforts of the surgeon doubly hard as he must overcome their tendency to give up after a week or two of painful experience. A very necessary adjunct to be constantly held out to the patient is the fact that the condition is curable no matter what the character of the lesion in the bursa.

Dr. David Silver of Pittsburg said that he found in these as well as post-operative cases it was very much better to put them up to the full limit of motion once a day, then let them alone. He had not found it necessary to use a splint, but kept the arm in a sling and used manipulation; put them through the whole range of motion and found that they came out very nicely. He thought an error was made in diagnosing these cases as rheumatic instead of trying to find out what the real condition was.

Dr. William H. Cameron of Pittsburg said he dealt almost entirely with subacute and chronic cases and some of these supposed to be rheumatism came to his office and he seldom found that the case had been examined. The doctor never went into the history. One must examine all these cases if he wants to find out anything at all.

Dr. T. Turner Thomas of Philadelphia said that he had been making some studies on the cadaver in the last year in connection with these cases. The bursitis theory is being rather rapidly and generally accepted in this country to-day and is gaining ground abroad, still he did not believe that the cause of the trouble in these cases was in the bursa. They are due to a periarthritis but not one localized to the bursa.

Dr. G. G. Davis of Philadelphia believed that there was such a thing as a bursitis induced by disease in the same way that a person could get housemaid's knee in rheumatoid cases; also that bursitis, subacromial or subdeltoid, could be due to an injury. When the joint was moved it moved to a certain extent and then it was stopped by the ligaments. It was not stopped by the bursa. The bursa having nothing to do with the strength of the joint.

Traumatic Lesions of the Brachial Plexus and Its Component Roots.—Dr. Charles K. Mills of Philadelphia presented this paper and said that lesions of the brachial plexus and its component roots were usually of traumatic origin, the few cases not instances of traumatism being examples of a neuritis due to infection or toxemia and rare cases of neuromata and of hemorrhage into the plexus or its roots. He referred to the literature of the subject, recalling especially cases of gunshot injury, recorded by the Mitchells, examples of obstetrical paralysis with Klumpke's symptom complex, and cases due to fracture of the clavicle, dislocation of the shoulder with torsion of the plexus, and injuries to the spinal column and the roots of the plexus. In one case which was discussed in the paper the injury to the plexus resulted from a man falling from a third story window and striking the patient upon the head, the shoulder, and back. In this case, as subsequently determined by a unilateral laminectomy, the cervical roots from the fifth to the first thoracic were literally torn from their connections with the spinal cord. The diagnosis is to be made in the first place from affections like hysteria and various forms of organic paralytic disease. The diagnostic points of most value in distinguishing from hysteria are the absence of atrophy, electrical changes in the nerves and muscles, and also the retention of the deep and superficial reflexes in the hysterical case. The sensory changes if carefully studied have a different topography, those of hysteria being glove-like or assuming some other form not related to the nerve supply; those of root and plexus lesions following the peripheral or root distribution of the sensory nerves. Emotional crises may be present in the hysterical and organic cases. Dr. Mills in conclusion discussed the prognosis and treatment, especially considering the importance of surgical procedure in traumatic cases.

Dr. Charles H. Frazier of Philadelphia said we had two groups of cases, those in which we operated and found the plexus embedded in a mass of cicatricial tissue, and in which after the removal of the cicatricial mass and careful, well planned nerve anastomosis, the results of the operation were very unsatisfactory, and a second group in which at the operation no gross macroscopic lesion was demonstrable even though patients may have been subjected to the same character of injury. The operation of laminectomy for relief of traumatic neuritis, such as brachial neuralgia, the tabetic crises, excessive pain for inoperable tumor of the cord, should be resorted to much more frequently than it was. It was not nearly so formidable an operation as in the past.

Dr. T. Turner Thomas of Philadelphia said that the extravasation of blood around the nerve due to injury produced a condition which probably explained a good many of the so-called traumatic conditions in which the plexus itself was supposed to be injured.

Fracture of the Shaft of the Femur, End Results.—Dr. W. L. Estes of South Bethlehem read this paper, saying that one must make a sharp distinction between good functional results, and satisfactory cosmetic and functional end-results, in estimating his success in the treatment of a fracture. One must differentiate his results into two classes: 1st, Patients who immediately after union were able to use the affected member properly; and 2nd, patients who acquired good use of the member after comparatively long periods. Less than a dozen cases have ever left his hands with an ideal result, namely no appreciable callus, no shortening, no deformity, and perfect function. The open method of treatment of fractures was the best for most cases of adults who were treated in a clean and well conducted hospital.

Dr. G. W. Guthrie of Wilkes-Barre said there was no doubt that the future would justify the open method of treatment of fractures of the femur as well as other fractures of the bony structure. He had never treated an open compound fracture where he could make perfect adjustment and perfect fixation of the fragment that he ever regretted.

Dr. David H. Strickland of Erie said a large majority of fractures occurred in laboring men who could ill afford to be confined to bed; they had a family dependent upon them and consequently the quicker they were restored to usefulness to the support of their families the better our reputation would be. We ought not to pay very much attention in this class of cases to cosmetic surgery. If we got a good limb that enabled a man to perform his work as he did previous to his fracture, it was very much better that we return him to duty as early as possible than that we should return him with a beautiful limb.

Dr. Charles E. Thomson of Scranton made a plea for better and repeated attempts to reduce fractures without cutting. Two years ago he had two physicians with fractured thighs under his care. He reduced one of these cases twice.

Dr. J. T. Rugh of Philadelphia said that the open operation for fracture was a difficult one and a big one, and if undertaken extensively by surgeons generally would have a very extensive mortality.

Dr. John B. Roberts of Philadelphia said that there were three kinds of fracture: those which could be treated well if they were opened, a middle class, and a class which could be treated best by opening. The whole question depended upon the fact that the man who undertook to reconstruct that portion of the bone must know his anatomy. Don't open a fracture unless you know something of aseptic surgery, don't treat a fracture unless you know anatomy of the part and its relationship with the surrounding parts,

and be careful not to believe all that the skiagraph appears to show. There is nothing that lies so much as a skiagraph taken by a man who knows nothing of anatomy.

The Surgical Reconstruction of the Human Skeleton.—Dr. JOHN B. ROBERTS of Philadelphia read this paper. He said that all operative and mechanical procedures designed to correct congenital or acquired deviations of the bony framework of the body were included under the caption Surgical Reconstruction of the Human Skeleton. Recent developments in physics and surgery had greatly widened the field of osteoplastic and osteogenetic reconstruction. We were no longer limited to curing broken bones, removing supernumerary digits, straightening bowlegs and knock knees and improving lateral curvatures of the spine. We could lengthen or shorten the limbs, convert solidified joints into movable ones, substitute the fibula for the tibia, successfully repair osseous lesions that formerly left hideous deformities, and transform many useless members and parts into satisfactory substitutes for normal structures.

An Operation for Ankylosis of the Hip Joint in Which Baer's Membrane Was Used.—Dr. G. G. DAVIS of Philadelphia presented this paper giving the history of a girl of 10 years with bony ankylosis of hip in a somewhat flexed position due to a previous rheumatic attack. Incision was made below anterior superior spine of ilium. The head of the femur was solidily united by bone to pelvis. The bone was cut away in the line of union. The head of the femur was enveloped by a sheet of Baer's membrane (chromicized pig's bladder), held in place by chromicized catgut. The wound was closed and a drain left for 24 hours. Position of the limb was good about five months after operation. The patient suffered no pain on walking; there was slight shortening, and the thigh was flexed to an angle of about 45°.

Dr. J. T. RUGH of Philadelphia said that there was no doubt that the method proposed by Dr. Baer was a very decided advance over any method previously employed in selected cases. In those cases in which there still remained some of the articular structures there was no doubt of the value of chromicized pig's bladder.

Spina Bifida and Its Surgical Treatment with a Description of an Efficient Osteoplastic Operation.—Dr. W. WAYNE BABCOCK of Philadelphia presented this paper and said that the features of the operation which he performed were a vertical suspension of the patient with the head dependent to limit shock and the leakage of cerebrospinal fluid, local anesthesia; the return of the distended inner layers of the sac to the canal without extensive isolation or injury to adherent nerve trunks. If no semblance of a canal is present a sufficient groove is cut into the spine or sacrum; the isolation of the edges of the dura and their accurate suture over the cord; the mobilization of a ribbon of bone upon either side of the defect which is left attached above and below. For this purpose the rudimentary laminæ or bases of the spinous processes are divided by Satterlee's bone forceps. The two osseous double pedicled flaps are united in the mid-line. The isolation of two broad double pedicled flaps consisting of the outer layers of the erector spinae muscle and their overlying aponeurosis which are slid inward over the bone flaps and united in the median line by buried chromic catgut. The union of the everted edges with skin by means of mattress and interrupted sutures without drainage.

Dr. STEWART L. MCCURDY of Pittsburg said that one of the most difficult things, especially in the surgery of children born with defects, was spina bifida. There was no one condition that had called forth the ingenuity of the surgeon as this. There had been as many different methods used to close the defect as operators almost. The one which had been presented by Dr. Babcock was certainly very admirable.

Wednesday, October 5—Second Day.

Oration on Surgery: Surgery, Past, Present and Future.—Dr. JOHN B. DEAVER of Philadelphia gave this oration, saying that every race in every age had flattered itself that it was the true age of progress and believed that the like could never be seen again. The surest antidote to such complacency was to realize how often this had proven false in the past. The surgery of the past had been notable chiefly for the establishment of a few underlying principles upon which all our modern practice was based. For centuries men had been content to have pus and even praised it if it were of that consistency and character which was thought proper. Then as now the object of the surgeon was to get his patient well and he gave less thought to originating epoch-making innovations applicable to all surgery than to the individual problem presented by his patient. It had been accordingly only after ages of groping among details that principles began to emerge. The period did not lack for men of boldness and ingenuity, but they suffered from a lack of these underlying essentials of successful surgery. The present era of surgery dated from the discovery of anesthesia by Morton and the practical recognition by Lister of Pasteur's discoveries. The surgery of the present was remarkable for the elaboration of method and technique and the rise of surgical pathology. With the introduction of new methods surgery had found its main field in the body cavities, regions previously secure from entrance. Also operations for cancer and upon the vascular system had been vastly improved. Abdominal surgery had been opened up as a new field. The surgery of the pylorus and the pancreas was being rapidly developed. Dyspepsia had been found to rest usually upon an organic basis. The surgery of the pelvic organs and the genitourinary tract had reached a plane of efficiency where it waits upon improvement in diagnosis and early reference of patients. The surgery of the head had advanced *pari passu*. Its contents responded to the same principles as in surgery elsewhere. The surgery of the thoracic cavity had lagged behind on account of the difficulties of practical application of surgical principles. This problem belonged to the future. The treatment of infections would be greatly aided in the future by sera and vaccination. As yet the early application of the aseptic scalpel reigned supreme as the cure of tumors benign and malignant. Every tumor should be considered malignant until proven benign.

Pathology and Treatment of Acute Bone and Joint Infections.—Dr. JOHN B. MURPHY of Chicago (by invitation) delivered this address. Dr. Murphy said that ankylosis of joints occurred only where the bony surfaces came into contact. Therefore, in acute joint affections, to prevent ankylosis, extension should be put on. In the second place tension must be relieved not by incision, as that leads to obliteration of the cavity, but by aspiration. Following aspiration there should be injected into the joint a 2 per cent. solution of formalin in glycerin. In acute osteomyelitis in order to prevent destruction of bone it was essential to relieve pressure at once. This could be done with a knife and a gimlet. In case the bone was destroyed it could be restored by transplanting.

Acute Dilatation of the Stomach. Report of a Remarkable Case.—Dr. ERNEST LAPLACE of Philadelphia read this paper saying acute dilatation of the stomach was very fatal, 63.5 per cent. dying. It was not as rare as the literature leads us to believe. This was shown by the rapid increase in the number of cases reported since the subject had become better known. The stomach tube was the immediate resource. When, however, the condition was more accentuated a large gastroenterostomy should be performed to effectually and permanently drain the stomach. The rarity of this condition should be no excuse for our overlooking its possible existence in a given case for

an early diagnosis might by washing out the stomach prevent a condition which would prove fatal in a few hours.

Chronic Gastroduodenal Dilatation.—Dr. George P. Müller of Philadelphia read this paper saying that the etiology of postoperative dilatation of the stomach was still obscure; dilatation of the stomach being considered by some as primary and by others as secondary to compression or kinking of duodenum. The chronic type had been reported in only a few instances but may have a similar etiology.

Dr. John H. Musser of Philadelphia said that the only case of dilatation of the stomach he had seen was one that appeared to be due to defective innervation. He had been on the lookout for gastroduodenal dilation, but confessed that he could not during life make the diagnosis of the condition.

Diffuse and General Peritonitis.—Dr. John J. Buchanan of Pittsburg read this paper, saying that the best treatment of peritonitis was its prevention. The bulk of the cases are usually the result of perforative appendicitis and can be prevented by removal of the appendix within a few hours or a day of access of first pains. Purgation was the most deadly medication that could be employed in acute appendicitis or diffuse peritonitis. Immediate operation, or at least during first 24 hours, by removal of appendix, dry mopping, closure of abdomen without drainage can be relied on to cure almost every case of free, diffuse or spreading peritonitis from perforative appendicitis. Treatment by irrigation was disseminative of septic products and should not be employed. Even the earliest operations can not yet be relied on to check the spread of peritonitis from perforated gastric ulcer, and in these cases the delay of a few hours may mean death for the patient.

Dr. John B. Murphy of Chicago said that he has had 64 consecutive cases of perforative peritonitis with 62 recoveries. This did not include the appendiceal abscesses or appendicitis cases with large quantities of pus that did not communicate directly from the alimentary tract into the free peritoneal cavity. He felt that we as a profession must come up to the standard that all of the cases of appendiceal peritonitis with the exception of 1 per cent. of primary perforation were avoidable. The diagnosis could and should be made before the perforation.

Diagnosis of Duodenal Ulcer; Indications for Operative Intervention.—Dr. John H. Gibbon of Philadelphia read this paper, stating that the pain of duodenal ulcer came two to four hours after ingestion of food and was apt to keep up until the next meal was taken. The pain was a steady ache, might be referred to the back or right mammary region, and was accompanied by a sense of fullness in the upper abdomen. The pain was also relieved somewhat by eructations of gas, vomiting, lavage, and alkalies. The pain would last a few days to a few weeks with an interval of comfort. Blood in the vomitus or stools was a late symptom and diagnosis should be made before this occurs. Gastric analysis was of very little value. Every case of chronic duodenal ulcer should be subjected to surgical treatment. In early cases a cure might be obtained by medical treatment. Never do any operation upon the gastrointestinal tract for ulcer unless ulcer could be plainly demonstrated.

The Indications and Technique of Partial Gastrectomy.—Dr. C. H. Frazier of Philadelphia presented this paper. He said that the resort to gastrojejunostomy in all cases was undesirable. This operation was suitable for ulcers of the pylorus when causing obstructive symptoms. Pre-pyloric ulcer and saddle-back ulcer not causing obstruction should be removed by resecting the pyloric portion of the stomach. Ulcers far distant from the pylorus, as in the fundus, should be removed by partial excision. In the development of the radical operation for carcinoma of the pyloric portion of the stomach, too little attention was paid to the topographical anatomy of the lymph nodes. Operation to be radical should include removal of the six primary lymph chains, namely, the suprapyloric, inferior coronary, right paracardial, gastrocpiploic, subpyloric or retropyloric, and the suprapancreatic. The retropyloric were the most frequently overlooked and the supra pancreatic the most difficult to remove.

Delayed versus Immediate Operative Treatment of Terminated Ectopic Pregnancy.—Dr. C. A. Stillwagen of Pittsburg read this paper, stating that hemorrhage and shock in terminated ectopic pregnancy were rarely sufficiently severe to cause death. In cases in which hemorrhage was severe and persistent death not infrequently resulted before operative treatment could be instituted. Patients who survived the initial hemorrhage, but were profoundly shocked and anemic, could be more safely treated by delaying operation until the condition improves than by immediate laparotomy. Operation should be performed as soon as possible after termination of ectopic pregnancy, provided it could be done with safety to the patient. In selecting the time every surgeon will, of course, use his own judgment, but he must show a low mortality in order to justify any given plan of procedure.

Surgery as a Prophylactic Measure Against Intestinal Complications in Typhoid Fever.—Dr. L. J. Hammond of Philadelphia read this paper, saying that when, during the course of typhoid fever, there was reasonable certainty of the existence of bands or adhesions, especially affecting the functions of the intestinal tract at any of its flexures, sufficient to produce severe abdominal symptoms, exploratory laparotomy should be done with a view to removal of mechanical barriers to intestinal activity which favor ulcerative processes going on to perforation.

Dr. G. L. Hays of Pittsburg said that in his experience in about 50 cases of operation for complications of typhoid fever none had shown any preperforative signs. While it was possible he doubted if they were very frequent. Of course if we could prevent this condition by any means by operation he thought it would be a very good thing to do.

Treatment of Stab Wounds of the Chest with the Demonstration of a New Intratracheal Cannula for Any Positive Pressure Apparatus.—Dr. G. M. Dorrance of Philadelphia read this paper and stated that hemothorax was the complication which determined the method of treatment; when this was present immediate operation was advisable. The chest should be opened, clots and serum removed, wounds in the lung sutured and the chest wall closed, the lung being expanded by negative or positive pressure. An apparatus for artificial respiration during thoracic operations should be simple, easily operated, cheap, portable, capable of being operated by hand power in case of necessity; it must not damage the larynx. The Matas clinical respiratory apparatus with the intratracheal pressure bulb tube which Dr. Dorrance had devised closely approximated these conditions.

The Relative Value of the Various Methods for the Determination of Kidney Sufficiency.—Dr. B. A. Thomas of Philadelphia read this paper, saying that the most accurate and dependable test for the determination of renal function was that by quantitative metabolic study, but such study was usually impossible. Any test dependent upon synchronous catheterization of the two ureters had a limited field of application. The cystoscope together with one of the aniline dye tests, notably indigocarmine, afforded the most practicable means of kidney diagnosis.

Results of Gallstones.—Dr. J. A. McGlinn of Philadelphia read this paper, saying that in eight out of eleven cases of cancer of the bile-duct stones had been present. In a series of autopsy records of gallstone cases various

related lesions were noted. While it could not be said that all these lesions had been due to gallstones, many undoubtedly had been. These lesions could be prevented only by early operation in gallstone cases.

The Pelvic Fascia with Reference to Operation for Cystocele.—Dr. R. E. Brenneman of Pittsburg read this paper, saying that the bladder and anterior vaginal wall were attached to the white line which gives rise to the levator ani and by cutting these attachments a cystocele is produced by downward pressure. These protrusions of the anterior vaginal wall, either lateral, bilateral, complete or partial, must be considered true herniæ and were produced by a variety of cases. These were repaired by restoring the normal anatomy, as far as possible. This was best done by the method of White of Savannah which the author has used in several cases with success.

Cecostomy versus Appendicostomy for Colonic Irrigation.—Dr. William M. Beach of Pittsburg read this paper, stating that the comparative safety of cecostomy is apparent. Cecostomy or appendicostomy should always be considered as an adjuvant to medical measures to be invoked in order to treat local conditions locally. It should be considered a legitimate treatment of toxemias of intestinal origin, amebic dysentery, obstinate colitis and constipation, tuberculosis and syphilis and it is believed to be justified as an adjunct to medical measures in anemias, intussusception and typhoid fever.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 6, 1910.

The President, Dr. John A. Wyeth, in the Chair.

Report of the Trustees and Council Relating to the Recent Purchase of Adjoining Properties.—Dr. John H. Huddleston, the Secretary, said that the Academy had recently acquired adjoining property and the house abutting on Forty-fourth Street in order to enlarge the building. Particulars of the change were given in the Medical Record of September 10, page 453. This matter will come up for final action at some future meeting.

Amendment to Constitution.—An amendment to the constitution was offered to raise the limit of non-resident Fellows from 150 to 250.

More Money for the Use of Library.—It was moved that the sum of $500 be voted for the use of the library. This was in addition to the sum already given.

Presentations.—Dr. Chas. E. Denison presented to the Academy a photograph of Baron von Humboldt. Dr. Paul Bartholow of Philadelphia presented to the Academy a photograph of Professor Bartholow who for many years was connected with Jefferson Medical College of Philadelphia. D. W. Johnston presented an engraving of Dr. William T. Bull. These gifts were all accepted, and the secretary was directed to send the thanks of the Academy to each of the donors.

Report of the Committee on Finance.—Dr. L. Emmett Holt stated that there were 1208 members of the Academy and at least four-fifths of these would contribute something; therefore, the Committee had elaborated a scheme of contribution as follows: It was assumed that 300 members would give $5.00 a year for five years; that 200 members would give $10 a year for five years; that 150 members would give $25 a year for five years; that 125 members would give $50 a year for five years; that 100 members would give $100 a year for five years; that 50 members would give $200 a year for five years. By such a scheme he said that from $150,000 to $200,000 should be raised.

The Definition of Pernicious Anemia and Its Treatment.—Dr. E. Grawitz, Professor of Pathology of the University of Berlin, made this address. (See page 751.)

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of October 22, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	515	163
Diphtheria	253	18
Measles	75	2
Scarlet Fever	90	3
Smallpox	—	—
Varicella	44	—
Typhoid Fever	108	20
Whooping Cough	24	2
Cerebrospinal Meningitis	2	2
Malarial Fever	—	—
Totals	1,111	210

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended October 21, 1910.

PLACE	DATE	CASES	DEATHS.
CHOLERA			
Austria-Hungary: Budapest	Sept. 8–24	6	1
Sept. 29, still present			
Kalocsa	Sept. 23		Present
Neusatz	Sept. 23		Present
Preesburg	Sept. 23		Present
Chica: Amoy	Aug. 28-Sept. 3	1

THE EHRLICH-HATA (606) PREPARATION.

(THERAPIA STERILISANS MAGNA.)

A REVIEW OF SOME OF THE REPORTS MADE BY GERMAN AND FRENCH PHYSICIANS UPON THE TREATMENT OF SYPHILIS BY THIS PREPARATION.

By JOHN BETHUNE STEIN, M.D.,

NEW YORK.

ASSISTANT IN THE DEPARTMENT OF GENITOURINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

No place perhaps lends itself so well to the study and treatment of syphilis as Finger's Clinic at the Allgemeines Krankenhaus, Vienna. For there, adjoining the dispensary, is the laboratory (serodiagnostic investigation station) where not only the seroreaction of the patient is studied, but examinations by means of the microscope and dark-field illuminating apparatus are made of specimens taken from various syphilitic lesions in order to determine the presence of the *Treponema pallidum* (*Spirochæta pallida*); while above stairs are the wards for the patients suffering from venereal diseases. In one of these (the now called historical ward) there were no less than 35 cases, all of whom had received an injection of 606. The results seen there by the writer form the incentive for this review.

The attention of the entire medical as well as the lay world has been for some months past seriously fixed upon the treatment (*therapia sterilisans magna*) of syphilis by means of the new preparation recently discovered by Geheimrat Ehrlich in Frankfurt, Germany. Needless to say, not only he who makes the study and treatment of syphilis his specialty, but the medical profession as a whole and the world at large, await the results obtained with not a little particular interest.

As the first field of experiment with 606 was in Germany, and as the greatest number of diverse cases of syphilis and parasyphilis, now amounting to several thousands, have been treated with this drug and studied for some months past in the numerous clinics where German is spoken, the facts here presented will be taken mainly from German and French writers.

In September, 1909, Prof. Conrad Alt of Uchtspringe (Altmark) received from Ehrlich an arsenical preparation, named dioxydiamidoarsenobenzol, having the formula $C_{12}H_{12}O_2N_2As_2$, the clinical value of which he was requested to prove in the treatment of syphilis in man. The preparation was actually made by Dr. Bertheim, a coworker of Ehrlich's, and the investigation of the effect of the drug upon animals was conducted by Hata (a pupil of Kitasato). They were able with this preparation to cure relapsing fever in rats and mice after a single injection; and it was further shown that the drug had an action upon the syphilitic process in rabbits which were infected with this disease. There were 605 different preparations experimented with before the 606th was selected; hence the name, Ehrlich-Hata (606).

The preparation was first used upon a man in Uchtspringe; but not before it had been tried upon dogs as a precautionary measure, in order to prove its harmlessness. Later two healthy physicians presented themselves for experimentation and allowed themselves to be injected with a dose of the drug to show that it had no deleterious effects upon the human organism. The physicians suffered no ill results, except considerable pain for several days in the region where the injection was made and where there was some swelling. Ehrlich said that 606 was not organotropic and that it had a high parasitotropic value. Both of which statements thousands of experiments have proved. Hoppe was the first who actually tried the drug upon man.

The Technique.—Dioxydiamidoarsenobenzol is a bright yellow powder, not pure, but an acid salt and might more properly be called a dichlorhydrate of the dioxy-diamido-arsenobenzol. It is put up in tubes *in vacuo* and before the preparation is used it must be converted into a sodium salt.

The solution to be injected should always be prepared immediately before it is needed as it cannot be sterilized after it is ready for use. Rigorous asepsis is necessary in its preparation. All instruments, pipettes, mortars, pestles, stirers, etc., should be sterilized either in an alcohol or a Bunsen flame and the various solutions sterilized either by boiling or by some other means. The technique for the preparation of the drug for injection differs with different experimenters.

1. *Alt* prepared the solution in the following way: There was placed in a measure glass (capacity of 50 c.c.) a single dose 0.3 gm. of 606 (at that time they never used more than this) and about 10 c.c. of sterile water added. It was well shaken up; then a sterile normal solution of NaOH was added until only a small amount of the substance remained undissolved. It always needs for this about 2 to 2.3 c.c. normal NaOH. After this 20 c.c. of sterile water is added and 10 c.c. of the fluid is slowly but forcibly injected deeply into the right and left gluteal muscles respectively. The 20 c.c. of water are added usually after the addition of some anesthetic. After the injection, the patient is ordered to lie on his belly and remain so for half an hour.

2. *Procedure of Herxheimer.*—A medium dose (0.5 gm.) is used, which is very carefully triturated in a mortar, to which is added 0.3 c.c. of a 20 per cent. solution of NaOH. The trituration is continued and finally there is added little by little 10 c.c. of water. The fluid is injected immediately in

order to avoid a sort of coagulation which is liable to occur.

3. *Blaschko* also employs a 20 per cent. solution of NaOH (Sp. Gr. 1025), of which he adds 0.09 grm. per decigram of the powder treated, that is 0.36 c.c. of a 20 per cent. solution of NaOH are used for a dose of 0.5 grm. of 606. The powder is slowly triturated and finally 5 to 6 c.c. of very hot, boiled water is added.

4. For a dose of 0.5 grm. *Michaelis* pours on the powder, which has been placed in a test tube, 1 to 2 c.c. of ethyl alcohol, and gradually adds 20 c.c. of very hot distilled water. While doing so the tube is to be shaken vigorously. When the solution is perfect he adds 1 c.c. of a normal solution of NaOH (40 parts in a 1000 per decigram of the powder). To this fluid he adds 2 or 3 drops of a ½ per cent. solution of phenolphthalein. The color of the solution becomes red. He then adds a few drops of a normal solution of acetic acid until the preparation is colored a sulphur yellow. At this moment 2 or 3 drops of the alkaline solution is added to neutralize the excess of acid. When a rosy halo is formed at the upper part of the fluid it is ready for use.

5. *Wechselmann* made the solution as follows: A given dose, which in the tube is *in vacuo* and is really an acid salt, a dichlorhydrate of the diamidoarsenobenzol, is mixed, with either methyl alcohol or glycol until dissolved, then 10 c.c. of distilled water is added, then 1 to 2 c.c. of a decinormal NaOH solution, to which is added 25 c.c. of water and this strongly acid solution is then injected. Later he added the decinormal NaOH until the fluid was cloudy, whereby a monochlorhydrate was formed. The concentration of the solution or the fact that the drug was dissolved in water appeared to produce very little difference in the pain at the seat of injection. Wechselmann now adds decinormal NaOH solution until he obtains an alkaline reaction with phenophthalein and neutralizes the solution with 1 per cent, acetic acid. This preparation of the drug is cloudy, and whether its action is as rapid as that of an absolutely clear solution we do not know; however, an absolutely painless injection may be efficacious. The place where the injection is to be made can be entirely anesthetised by a deep injection of 0.02 grm. novocain.

The syringe should be an instrument easily sterilized, have a capacity of 10 c.c., with a platinum-iridium needle of large caliber and about 6 c.c. long. In Germany they frequently used a Record syringe. An automatic syringe for intravenous injection is made by B. B. Cassel in Frankfurt.

The region where the injection is to be made should be thoroughly washed and cleaned with alcohol and ether and finally painted with tincture of iodine. Various points may be selected for the introduction of the drug, the buttocks, the back between or below the scapular or the chest in the submammillary region. The injection can be subcutaneous, intramuscular, or intravenous when it is desired to get a particularly rapid action of the drug upon the lesions, for with the intravenous injection the symptoms subside more quickly. The intramuscular injection is made in the buttocks or such places as are selected to inject insoluble mercurial preparations.

Wechselmann and many other experimenters prefer the intragluteal injection. The injection is made in the same manner as we make those of insoluble mercurial preparations. Slowly and forcibly about 10 c.c. of the fluid is injected deeply into the right and left gluteal muscles. The solution flows imperfectly, as it forms itself into a sort of light, salty coagulate which often leads to the blocking of the syringe. From 5 to 25 c.c. may be injected, following the quantity of the fluid and the capacity of the syringe. 606 may be suspended in paraffin oil and then injected. The volume is less.

Dose.—Alt gave at first only 0.3 grm. Wechselmann gives 0.45 grm. to women and 0.6 grm. to men. Some give as much as 0.7 grm. without harmful results. The average dose is 0.5 grm. Schreiber repeated the injection after four weeks in four cases where there were relapses. Neisser employs the intravenous method whenever possible. Gérrone and Huggenberg treated 56 cases since April 2, 1910. Twelve by the intramuscular injection (0.3 grm. 606) and 23 by the intravenous 0.3 to 0.4 grm. of 606, according to the body weight.

The volume of the solution to be used for intravenous injection is 100 c.c. containing 0.4 to 0.5 grm. of 606. Schreiber recommends that it be still further diluted, for in that way it may be able to avoid the skin eruptions which may by chance follow the administration of the drug. Michaelis advised that the seat of injection be massaged for at least 10 minutes after the injection, in order to assist the absorption of the drug.

After the injection the seat of operation is again painted with iodine and covered with sterile gauze which is held in place with adhesive plaster.

One of the most important points, which the medical man as well as the layman should know, is the absolute necessity for the patient to remain in bed for the first two or three days after the injection, and in his room for a period varying from six to ten days. These precautions must be taken as much for the observation of the local reaction at the seat of injection as for the general condition of the sufferer. The drug should not be administered to patients in dispensaries or to those who will not submit to the exigencies which the injection demands. The injection, which is not painless, is accompanied by some reactions both local and general, the importance of which should not be exaggerated, particularly when the injection has been made with great care; nevertheless, they are at times so active and evident that it is necessary to assure the patient he is in no danger.

The Reactions.—1. *Pain,* which is often tolerable, at times acute, appears some hours after the injection and reaches its maximum in 12 or 24 hours. The pain lasts for one to six days. In rare cases where it is intolerable applications of ice and an injection of morphine must be given. At times the pain persists in an attenuated manner for several days. Gérrone and Huggenberg have seen cases where the pain radiating to the back and legs lasted several weeks. These pains radiating to the legs and thighs cripple them. They have mistaken this crippling for a paralysis of the legs. There is more of a dull ache than a real pain, nevertheless it sometimes persists for a long while. At times the pain is only local. With the intramuscular method very great local pain was noticed (Gérrone and Huggenberg).

2. The inflammatory swelling resembles the local reaction produced by a large injection of calomel. The subcutaneous injections, without being more painful than the intramuscular, often seem to favor the appearance of this swelling. When the vehicle of the drug varies between 15 and 25 c.c. the swell-

ing appears immediately. The swelling is at times accompanied with a redness of the skin, which at first sight appears as if an abscess was forming, but there is no fluctuation on palpation. The tumor is firm, scarcely depressable and generally painful when palpated. According to Neisser, in most cases after an intramuscular injection, the hard infiltration and pain disappear without leaving a trace in six or eight days. Tomaszewski states that the painful infiltration lasts fourteen days and is accompanied by a rise in temperature (100.4° F.) lasting several days. If the technique, aseptic and operative, is not at fault no complications should follow. Wechselmann punctured the infiltration in one case.

3. A *rise in temperature* appears with a medium dose (0.5 grm.) once in four or five cases. The rise in temperature is slight, particularly if the patient is not imprudent. Sometimes the oscillations of temperature are insignificant. The temperature continues to rise not over 12 to 16 hours and does not exceed 102.5° F. Gérrone and Huggenberg say the average temperature is 101.3° F., in one case 103.1° C., and in an old man 104° F. After intravenous injections of 606 in nonsyphilitics the fever does not occur. After the lapse of 24 hours the temperature sinks in each case to about 98.3° F. or 99° F. One hour after the injection the difference in temperature amounts to 2.16° F. to 2.7° F.

4. *Constipation* is usual; diarrhea at times follows a large dose. The latter is often met with when the febrile reaction is violent, with dryness of the throat and other signs of arsenical poisoning. Duhot considers the diarrhea a normal complication following the intravenous injection of a large dose. According to Gérrone and Huggenberg, with the intravenous method, there were quite constant symptoms of poisoning, which began one to two hours after the administration of the drug and were over in eight to twenty hours. With the intramuscular injection they observed no abscess, no symptoms of arsenical poisoning.

Frequently severe headache, nausea, vomiting, and great restlessness are observed (Spatz), cutis anserina, but no chills have been reported. The tormenting thirst, about which the patients chiefly complain, cannot be attributed to the fever alone, as it has been observed when the temperature was 99.5° F. (Spatz). In one case (Spatz) the heart's action was more rapid and irregular, accompanied by a general feeling of uneasiness. The same observer reports a case of polyuria (over two liters of urine daily) which lasted three to four days.

5. The consequent *eruptions* are quite frequent in patients who have specific eruptions and are generally limited to a sort of accentuation of the specific erythema. Frequently macular spots appear upon the skin the first few days (two or three days) following the injection. If the rash is a roseola it becomes congested, redder in color, increases in size and at times surrounds itself with a kind of macular eruption. If it is any of the types of a papular syphilide, the papules become surrounded by a sort of areolar or halo which makes the lesion appear as if suddenly aggravated. Sometimes a sort of nettlerash appears. In one case, six hours after the injection, there appeared upon the whole body and head "a bright red, elevated, itching nettlerash sort of infiltrate" which after two hours disappeared without leaving a trace (Spatz). Exceptionally are these drug eruptions of importance.

This consequent eruption is known as the Herxheimer reaction, or, more properly, Jarisch-Herxheimer reaction. Herxheimer considers cases, where the reaction is seen, as being infrequent and not at all constant, a sign unfavorable to healing and even heralding a new rapid growth of the lesions. Gérrone and Huggenberg report that half an hour after the injection (intravenous) the syphilitic eruption becomes intensely red, as in the Herxheimer reaction, "but exceptionally there forms in other parts of the body, free from the exanthem, an urticarial eruption." All these disappear in 24 hours. In their 35 cases treated, they only observed the eruption with an intravenous injection.

Schreiber reports three cases (he studied 150 injected cases) where the Herxheimer reaction appeared 12 hours after an intramuscular injection. After the intravenous injection of 606 the Herxheimer reaction appeared in a few hours. One patient developed an exceptionally severe exanthem three hours after the injection, the character of which Schreiber had never seen.

The cases which show a Herxheimer reaction, Wechselmann considers as having been given a dose of 606 too small to kill the *Treponema pallidum*, and that the reaction is an expression of a kind of biological excitement of the same brought about by too small a dose. A second injection can be tried in such a case, yet it is possible that this will be answered by symptoms of anaphylaxis, or be ineffective on account of the power the spirochetes have of withstanding the drug. In the last condition mercury can be used in order to destroy the remaining organisms.

Before we speak of the clinical results obtained by Ehrlich's method of treatment, we must note the striking efficiency of the method as attested by laboratory control. The search for the *Treponema pallidum* (*Spirochæta pallida*, or commonly called spirochetes) under the microscope, especially by means of Burri's or the dark-field illuminating method, combined with the examination of the patient's blood, in order to find its seroreaction according to the method of Wassermann, are indispensable complements of the clinical observations. They are both necessary in order to know at what point Ehrlich's treatment is efficacious.

Siesskind, the assistant of Wechselmann, found that the spirochetes disappear at about the end of a day (24 to 36 hours), but they may persist for several days (6 or 7 days). Before they disappear one can see that their vitality is greatly compromised; they appear swollen, their mobility is diminished or has disappeared and the refringence, so characteristic of them, is lost. Gérrone and Huggenberg could not find the spirochetes in the primary or secondary lesions after the day of injection; and in two cases, in which six hours after the injection the spirochetes were still found, they were fewer than before, and appeared rolled up and flattened with irregular windings. A. Neisser says: "We can say with surety that the new drug exercises an eminent, straight-away influence as well upon the spirochetes as upon the syphilitic products themselves. The spirochetes, not only in animal syphilis, but also in human syphilis, disappear in very many cases after 24 to 48 hours from the chancre and condylomata, where they previously were present in great numbers. The

Herxheimer reaction (a reddening and swelling of the macules and papules) which appears 24 hours after the injection is another proof." Neisser leaves the question open, as to whether the Herxheimer reaction is a question of the killing of the spirochetes by the preparation together with a freeing of the endotoxin or a sort of stimulation of the spirochetes and thence the ensuing rich secretion of the toxic material.

The reaction of Wassermann furnishes us with a means to determine and appreciate the decline of the infection after the injection of 606. Alt first used 606 upon 23 paralytics. In only two cases out of 18 which gave a positive Wassermann reaction did the positive reaction entirely disappear. Two showed a marked decrease, while three showed an appreciable decrease in reaction. Of 27 cases treated in Magdeburg by Schreiber, all gave a positive Wassermann reaction before the injection. Up to the time Alt reported these cases (a short time, not quite a month and a half), 4 of the 27 gave a negative reaction. "Two recent cases of chancre, which before the injection still reacted negatively to Wassermann, were positive eight days after, then they became negative after 14 days and have since remained so" (Géronne and Huggenberg).

Spatz reports nine cases treated by him. In six cases out of the nine, the Wassermann reaction was repeated on the twelfth day. In two cases the previously strongly positive Wassermann reaction became entirely negative. In three the reaction remained strongly positive. In one case of ulcerated chancre (spirochetes were present) in which the injection of 606 was given, while the Wassermann reaction was still negative, the negative Wassermann continued to persist after the injection. Emery states he has seen the reaction after the injection of 606 become negative in from three weeks to two months. "The disappearance of the reaction takes place slowly and progressively without submitting to those oscillations that I have encountered in mercurial cures" (Emery).

Neisser relates that in about 10 per cent. of the cases was the Wassermann reaction negative and only in those who came under treatment very early after the appearance of the chancre. A patient with a chancre (proved by the presence of spirochetes in the lesion) to whom the injection of 606 was given while his Wassermann seroreaction was still negative, became gradually positive, perhaps on account of the smallness of the dose given him (0.3 grm. to 60 kg. weight). Géronne and Huggenberg tell us (they treated in all 45 cases) the Wassermann reaction became negative in 10 cases after 4 to 10 weeks of observation. In 4 cases it remained positive (of 2 of the 4 cases 1 was 56 the other 70 days old). In the 25 cases which had been observed less than 4 weeks, the Wassermann reaction became negative in only 6 cases.

Hoppe and Schreiber found in the 52 cases treated by them, which they could observe 50 or more days, that after 50 days 84.6 per cent. of the cases which previously had a positive Wassermann reaction lost the same. Four other cases lost it later, thus making a total of 92.3 per cent. The earliest the reaction was negative was after 4 days; the latest after 70 days. Lange (an assistant of Wechselmann) examined the patients who were injected with 606 twice weekly in order to ascertain their seroreaction. Those who were long enough under observation showed a negative reaction. Comparative studies of the disappearance of the positive reaction of Wassermann in patients under treatment with the Ehrlich preparation and those with mercury have not as yet been sufficiently pursued in order to draw formal conclusions on the superiority of one or the other of these methods. Emery also states: "It was only just to recognize that if the mercurial medication has given me at times a precocious and complete negative seroreaction, I have scarcely ever obtained this negative and durable reaction, except after the application of a vigorous intermittent mercurial treatment carried on during three or four years."

Influence Upon Metabolism—Excretion of Arsenic after Injection, etc.—Alt observed that after the injection of 606 the lecithin metabolism was favorably influenced. The injection of the first fifty cases was made in Magdeburg under the direction of Hoppe of Uchtspringe. In each case exact investigations as to the metabolism of the patient were made, especially was the excretion of arsenic carefully studied. It was established that the excretion of arsenic was not so rapid as was intimated by other authorities. In some cases arsenic was excreted ten to twelve days after the injection. "With an intragluteal injection it is assumed that a sort of depot for the drug is formed, it is encapsulated as it were, and it cannot be recorded that on such and such a day will so and so much of the drug be taken from the place" (Alt). With intramuscular injections the arsenic is slowly absorbed. Ehrlich says that in hens injected, intramuscularly, with the *Spirillum gallinarum* it takes the infection thirty to forty days to develop; whereas after intravenous injection only three to four days. According to Ehrlich, muscle necrosis arises in the sphere of the injection which contains the preparation and slowly gives it up.

"From Magdeburg, two death are recorded for which the treatment with 606 was proved not to be responsible. In one of these cases fourteen days after the injection a considerable amount of arsenic could be found in a piece of the gluteal muscle. The other case, which thirty-six days after injection came to section, showed arsenic still present in the gluteal musculature (0.01 grm.). Doubtless, in a number of cases, where the intragluteal injection is given, a depot, so called, remains a long time. "If the dose is not effectual can we say it was too small, but is it not possible that the introduced drug did not come in contact with the several tissues of the recipient?" (Alt).

With intravenous injections of 606, the excretion of arsenic is almost ended after two days, only a trace being found after the third day. "During this time almost the entire amount of arsenic can be found in the urine and stools, a very small amount is found in the sweat" (Hoppe and Fischer). Hoppe and Fischer found arsenic in the urine of paralytics 10 days after the intramuscular injection of 606. They also report that after a subcutaneous injection in paralytics the excretion of arsenic in the urine (0.3 grm.) terminated after 12 to 14 days, in epileptics after 15 to 16 days, and with other syphilitics mostly before the fifteenth day. The excretion of arsenic from the intestinal canal, after an intramuscular injection of 0.03 grm. continued 10 days. According to Fischer and Hoppe arsenic was not found in the blood (30 c.c. of blood) 14 days after injection.

Heubner states that after the intravenous injec-

tion the excretion of arsenic is exceptionally rapid. Schreiber observed a light arsenical exanthem in two patients which appeared eight or ten days after the injection of 606, and very quickly disappeared. One of the patients had a rise in temperature. Hirschfeld found no changes in the blood except in a single case where there was a slight hyperleucocytosis. Schwarz also found a hyperleucocytosis. Neisser reports a hyperleucocytosis (3800) which appeared after an injection and which slowly declined. According to Heubner, even with the strongest concentration of 606, the formation of methemoglobin does not take place.

At the instigation of Fournier of Paris, Emery went to observe the experiments which were being made with the Ehrlich preparation at the clinics of Herxheimer (Frankfurt), Lesser (Berlin), Neisser (Breslau), and Wechselmann, Michaelis, Tomascyewski, Blaschko, Sachs, and finally Ehrlich himself. The experiences of Emery are of not a little value and on that account the writer will frequently draw from them.

Primary Lesion.—After Alt had found the efficient dose of 606 to be 0.3 grm. he had Schreiber try the drug upon recent cases of syphilis, in the Altstädtischen Krankenhaus in Magdeburg. Alt says: Since the 31st day of January, 1910, twenty cases of florid syphilis have been treated by us, each with a single injection (0.3 grm.) of 606, with immediate and astonishing results. The initial lesion itself, together with its induration, showed marked retrogression after a few days. The maculopapular eruption quickly healed, leaving pigment spots. Ulcerations on the labia are covered with epithelium in a few days. Large condylomata about the anus and perineum, in exceptionally bad cases, are entirely cured after four weeks. A large stubborn lesion on the head is after scarcely three weeks entirely cicatrized. In a few days the specific laryngitis disappears. There is, in all cases, an undeniable specific influence favoring the healing process. The tendency to heal is astonishing, dates from when the injection is given and there are no complications. With three exceptions the patients gained in weight. Pain at the site of injection and a rise of temperature (101.5° F.) were noted."

Emery says: "The action of 606 on a chancre of the lip appeared to me singularly rapid. It cicatrized in three or four days and the submaxillary adenitis disappeared as if by enchantment. The rapidity of action on the genital lesions was not quite so great."

I have seen chancres clear up in three days and cicatrize in seven, but the nodular infiltration, although softened and diminished in volume, persisted and the inguinal adenopathy slowly declined. Emery has seen chancres clear up in two or three days and cicatrize in five to ten days.

Ten chancres (Géronne and Huggenberg) about the size of a ten-cent piece were healed in ten to fourteen days. *A chancroid remained uninfluenced by* 606. The diminution in the size of lymph ganglia is especially rapid—eight to fourteen days. In most cases there remains a slight swelling of the lymph nodes and vessels.

On June 18, 1910, at 2.30 P.M., Wechselmann injected with 606 a patient suffering from about twenty roseolar spots upon the trunk and a dirty erosive chancre on the shaft of the penis. At 6.30 P.M. almost all the roseola had disappeared and the next morning the chancre was clean, almost without any induration, and on June 22, 1910, there remained of the lesion a mass about a lentil in size. Wechselmann recites a case of an initial lesion, the size of a dollar, which destroyed the lower lip. There was also a maxillary bubo, the size of a goose egg, upon which (in May) inunctions of mercury were used without much effect. On May 20 an intramuscular injection (0.04 grm.) of 606 was given. On June 2 the lesion was flat, about the size of a ten-cent piece, the glands small, and on June 8 the lesion was completely cured. A markedly indurated chancre (cartilaginous) observed by Wechselmann, cleared up rapidly, but the complete healing took a long time, a time corresponding to the resorbtion of the tissue growth.

Spatz employed the Ehrlich preparation in nine cases. The sum of results is the following: "The primary lesion, in six days, was covered with epithelium and was softened, the moist papules dried up and the macular eruption entirely disappeared."

Dörr treated twenty-six cases by the intragluteal injection and observed no complications other than a rise in temperature and a sensation of pressure at the seat of the injection. He says, "he must designate the instantaneous results as almost dumfounding." Some cases, which were injected before the symptoms of the secondary stage appeared, in which the nature of the disease was definitely established by the presence of the spirochetes in the initial lesion, accompanied by a positive Wasserman reaction, the initial lesion quickly disappeared. One case, which was injected shortly before the secondary stage, is still (one month later) free from all symptoms. It was the same with all cases treated by this so-called "preventive injection." The time, however, since they were treated is too short to give definite results.

The action of the drug upon the initial lesion is at times not so marked as it is upon other syphilitic lesions. This peculiarity has not escaped Ehrlich himself, but he says it is exceptional. Ehrlich told Emery of a chancre with an ulcerated center, where the spirochetes persisted, which would not heal, and which responded to treatment only when the mercurial treatment was added to his treatment. This fact is very unusual, as usually the spirochetes disappear in an extraordinarily short time in recent syphilitic lesions. The fact that there exists at times only a relative softening action by 606 on the chancre is explained, as Emery says, by the vascular thrombosis which partially prevents the drug from coming in contact with the spirochetes. The same phenomenon can be observed with the mercurial medication, particularly when we use insoluble mercurial preparations. Soluble mercurial preparations act upon the chancre with a much greater rapidity than insoluble; yet, nodular indurations persist for a long time. Who has not observed the nodular infiltration which persists after the chancre has healed? We should not call in question the efficacy of 606, at this period of the disease, because of these partial and exceptional failures and because at times its action upon the initial lesion is slow. The only syphilis which we can diagnose is a general syphilis. The syphilitic infection, as we know, is already beyond the limits of the chancre when it appears. There is a double generalization of the disease, one early and rapid by the blood vessels, the other late and slow by the lymph vessels. The seroreaction of Wassermann,

which is almost always negative three weeks to two months (Emery) after the injection of 606, attests unimpeachably the sure "sterilizing" action of the drug upon the human organism so far as the syphilitic infection is concerned.

The value of the reaction of Wassermann in the diagnosis of syphilis is universally recognized today. Practically, the reaction is a specific one. It is also certain that the reaction of Wassermann is a valuable indication not only as to the existence of the disease, but also as to the degree of virulence of the infection. It is clearly evident that the percentage of positive Wassermann reactions diminishes proportionately to the number of cures by the mercurial medication (Neisser). We must not, however, lose sight of the fact that the reaction gives indications only for a variable time and that a negative Wassermann reaction has been concomitant with the appearance of a localized tertiary lesion.

The only practical conclusion to be drawn from the foregoing observations is the necessity, if we wish to attempt to "sterilize" the body rapidly and completely, so far as the syphilis is concerned, of joining (as Blaschko has recommended) a local treatment (excision, destruction with the galvanocautery, or local mercurial treatment) with the general treatment of Ehrlich. Emery thinks the local and general mercurial treatment should be administered with 606. Ehrlich interdicts entirely the parallel use of another arsenical preparation such as atoxyl or hectine, but is not at all opposed to the concomitant or consequent use of mercury with 606.

Secondary Lesions.—The action of the drug upon mucous lesions of whatever nature and wherever located is most extraordinary. Mucous patches on the tonsils and soft palate, eroding syphilides, or superficial ulcerations of the lips disappear, as if by enchantment, twenty-four to thirty-six hours after the injection and sometimes there is not a trace twelve hours after the injection. Wechselmann cites a case of a young girl with severe mucous lesions of the tonsils, fauces, and labia pudendi which disappeared entirely eight days after an injection of 606.

Schreiber reports 150 cases treated by him, of which 128 were intramuscular and 22 intravenous. In all cases a prompt decline in the manifestations was noted. In ten cases, in which apparently the dose was not sufficient, new manifestations appeared before the expiration of four weeks.

Lesions of the vulva and penis, particularly when they take the form of vegetations and are bathed and irritated by the neighboring discharges, heal more slowly, but the action of 606 is none the less exceptionally rapid. In the service of Professor Lesser of Berlin very extensive vulvar lesions were healed in eight or ten days, the lesions simply being kept clean. Isolated and conglomerated condylomata regress, dry up, and disappear in almost the same time. At times, twenty-four hours after the injection the beginning of the drying up appears. Some disappear five or six days after the injection. Géronne and Huggenberg report that "small condylomata heal in fourteen days, ulcerated ones in two or three weeks."

The roseola and simple macules disappear in two to five days. Papules at the latest in three weeks. A hemorrhagic exanthem on the lower part of the thigh disappeared in eighteen days. With an impetiginous syphilide of the head and back, the lesions on the head disappeared in sixteen days and those on the back in three weeks. In five cases of laryngitis the laryngitis healed in seven to ten days.

The action, so extraordinary, so sure, and so rapid, of 606 upon eminently contagious lesions gives us a remedy which is destined to play a great as well as a first part in the prophylaxis of syphilis. The action of the drug on secondary skin lesions is very rapid. The roseola disappears more rapidly than a papular syphilide and much more rapidly than a papulomacular or follicular syphilide. Dörr states that in cases which had received Ehrlich's preparation after the manifestation of the secondary lesions or after a relapse the mucous and skin lesions (mucous patches, papular, macular, and lenticular syphilides) together with the local and general adenopathy declined in the course of a few days. There were no relapses in a space of time covered by one to four weeks. In many cases Neisser observed such a rapid decline of the initial lesion, the papular syphilide, the ulcerous processes, and especially the malignant types of syphilis that he says: "Regarding the specificness of the remedy no doubt can prevail."

Tomasczewski, coworker with Miekley at the University Skin Clinic (Berlin), injected (intramuscular, 0.3 gram 606) and observed seventeen patients with secondary syphilis. The manifestations of the disease promptly subsided, "in some cases surprisingly, and in one case astoundingly fast." Wechselmann reports two cases: one of pernicious anemia after syphilis with fever, dyspnea, and 20 per cent. hemoglobin, in which death followed eight days after an injection of 0.3 gram 606. The other case was one of papulocrustaceous syphilide of the worst kind, together with a rupial efflorescence on the forearm (1 cm. high and 2.5 cm. in diameter) from which, a few days after the injection, the crusts peeled off and there were left only small fresh granulating surfaces, and the syphilitic infiltration entirely disappeared.

There are different grades of resistance to treatment with 606 on the part of cutaneous lesions; the same can be observed when similar lesions are treated with mercury. Emery states that in some cases, where the mercurial treatment is vigorously used, where large doses of calomel or biniodide of mercury are given, the mercurial treatment compares very favorably with that of Ehrlich so far as rapidity of action is concerned. He has seen papulolenticular syphilides (they were considerably scattered over the trunk) disappear in less than three days, leaving behind only a light rose coloration. We all know how rapidly inunctions of mercury sometimes act upon cutaneous lesions.

The action of 606 upon the early malignant syphilides (pustular, ulcerous, ecthymatous, frambesioidal) is a veritable triumph. Not only are the lesions of the skin and mucous membranes rapidly and completely cured, but the general constitutional disorders which accompany them are *pari passu* ameliorated and disappear. The integument takes on its normal color, the fever and headaches cease, appetite returns, the patients gain in weight, and their general physical and mental conditions are reestablished in an extraordinary degree.

Alt recites a case of icterus syphiliticus, with very severe icterus, marked general adenopathy, and an extremely well-developed maculopapular syphilide. About nine days after an injection

(0.4 gram) the icterus had almost disappeared together with the eruption and adenopathy. Wechselmann also relates a case of syphilitic icterus healed by 606 in a week.

Dörr reports the following two cases of malignant syphilis: One a soldier, previous to his infection a robust man, who was treated for months with mercury and potassium iodide without any results. He was exceedingly pulled down, bedridden, unable to move himself, had night sweats and fever and his entire body was covered with an extensive crustaceous and ulcerated syphilide. His condition was such that his physician, Dr. Furhauf, gave a lethal prognosis. The patient was given a single injection, which on account of his decrepid condition contained only 0.3 gram 606; yet two days later the pain, fever, night sweats had ceased and on the third day the ulcers began to heal. He gained in weight and according to his own account felt exceptionally well. At the time of writing all the ulcers were covering themselves with epithelium. The second case (which was one of tertiary syphilis and is inserted here only for convenience) was in a woman who acquired syphilis five years previously and for four years suffered, in spite of all treatment, from a torpid ulcer about as large as the palm of the hand, which was 2 cm. deep and had an elevated sort of border. She was injected with 0.4 gram 606. Her condition became better at once, the ulcer, nothwithstanding its size and extensiveness, began to fill up with granulation tissue and the epithelium began to grow inward from the walls of the same. The injection produced no untoward effects in this patient, who was in a weak and reduced condition. Emery cites cases of infiltrated nonulcerated syphilides which healed in the same way although somewhat slower.

Herxheimer is of the opinion that localized ulcerater tubercular syphilides (forehead, wrist, arm, shoulder) heal less quickly than when they are scattered. Emery, however, says that the ulcerated tubercular syphilides heal as quickly as the nonulcerated.

Besides these secondary manifestations which are not easily or quickly cured by mercury or potassium iodide, there are other manifestations of syphilis, inveterate, deep, extensive, of the palm of the hand and sole of the foot, which are remarkable for their pertinacity and prolonged resistance to mercury. Emery saw two such cases. One in Ehrlich's laboratory which was "radically cured in a relatively short time." The other was in the service of Herxheimer, which was effaced about four days after an injection of 606. Géronne and Huggenberg relate two similar cases. One disappeared ten days after the injection of 606 and there was little to see of the other after seven days.

Comparison of the Ehrlich and Mercury Treatments.—Of special interest are some cases in which Wechselmann compared the results of the mercury and potassium iodide treatment with Ehrlich's treatment. He designates the following case as "quite unbelievable." Seven months previously the patient had a chancre and four weeks later an eruption. From November 28, 1909, to the middle of March, 1910, he received thirty-five injections of mercury. For three months he had pain in both knees and on May 5, 1910, he came under Wechselmann's care. "The patient was a skeleton, the skin sallow and corpse-like, his appearance that of a death's head, with an exceedingly painful expression." On the face and body were crustaceous lesions as large and larger than a ten-cent piece. Ulcers and scars of the same extended into the subcutaneous tissue. From the nose came a most offensive odor. The septum of the nose was perforated and the left inferior turbinated bone and vomer had sloughed away. Swallowing was very painful and the patient was kept alive by the stomach tube and nutrient enemata. The pulse was small, of low tension, and 120 or more. The end was daily expected. On May 21, 1910, Wechselmann injected 0.4 gram of 606. There was no rise in temperature and the pain remained moderate. Two or three days later the general condition was distinctly improved and on May 26, 1910, a general healing began. The diseased bone of the nose was thrown off *in toto*. The fetor vanished. On May 30, 1910, the lesions were healing or had healed, and on June 7 the patient began to swallow and go about. The weight increased from 84.7 pounds, on May 21, to 107.8 pounds, on June 22.*

Wechselmann also saw similar surprising results in two hopeless cases, which for years had been fruitlessly treated by the usual method. In one of these cases after an injection of 0.25 gram 606 the temperature rose to 102.8° F. and remained so during four days and morphine had to be given on account of the pain. Michaelis gives the following case with an idiosyncrasy toward mercury. On June 9, on account of an extensive papular syphilide covering the entire body, with psoriasis on the palms, and papules on the back of the hands, 0.3 gram of 606 was injected. No pain or disturbance was felt. The papules on the forehad and skin of the head began to disappear on the third day after the injection. On June 22, 1910, the only evidence of the disease were pigment spots on the backs of the hands. The following case of Michaelis offers another comparison of the two methods. A patient who contracted syphilis in 1906, in spite of mercury, atoxyl, and potassum iodide, had ulcers on the palate on either side of the uvula, and on the bridge of the nose. The uvula was ready to slough off. On the third day after the injection of 606, the edges of the ulcer became healthy and eight days after the injection on each side of the uvula was a small scar.

Pick reports two cases of malignant syphilis (ulcerated gummatous lesions of the pharynx and tonsils) on which mercury and potassium iodide were used without effect. The lesions began to heal a few days after the injection. The Wassermann positive reaction was not influenced by the drug.

Tertiary Lesions.—Particularly striking is the action of this drug upon all forms of ulcerated gummata. A case in Ehrlich's laboratory of an enormous gummatous ulcer of the leg was more than half healed (filled) five days after the injection of 606. The writer saw two very striking cases in Müller's service in Vienna. One a large ulcer of the face, the other of the leg, both of which were rapidly healing after the administration of 606, and which had previously resisted all treatment. It is a remarkable fact that the signs of periostitis, frequently so painful, beneath these gummata are the first to disappear. This is also the case in the other forms of syphilitic periostitis and the pain usually disappears the first night after the injection.

*Pick states that often with the rapid decline in symptoms the patients gain in weight (8.3 lb.).

Emery saw a case in Professor Lesser's clinic where two large gummatous ulcerations had developed in the middle of the dorsum of the tongue. The pain was so severe that the patient could only swallow liquids. Since 1900 the patient had taken mercurial inunctions and injections without staying the progress of the disease. Eight days after the injection the tongue was completely healed. In the middle of which was a linear fibrous cicatrix; the organ itself had its normal suppleness; all pain and inconvenience had disappeared, and, finally, he was shown a colored photograph of the intact lesions taken eight days previous. In the service of Herxheimer there was a gumma of the arch of the palate which had not been treated locally. Three days after the injection of 606 it showed a clean surface and cicatrizing edges. Michaelis cites the three following interesting cases from his service (Berlin): One was that of a pharyngeal and perilaryngeal gummatous ulceration which threatened the life of the patient. It was totally healed a few days after the injection of 606. The second case was one of syphiltic ozena; the repulsive odor from which disappeared forty-eight hours after the injection and was radically cured three weeks afterward. Von Zeisel and Duhot had the same extraordinary results with a diffuse hypertrophic syphiloma of the nose and upper lip after using Ehrlich's treatment. The third case was one of chronic syphilitic arthropathy which had resisted all treatment but yielded at once to 606.

Kromayer observed two cases of very extensive ulcerations (subcutaneous gummata) on the thigh, exposing the bones, which healed so quickly "as to be scarcely believable." He treated fifteen cases with 606,

The following two cases are taken from those reported by Géronne and Huggenberg. One, a gummatous orchitis, the size of a small fist, was sixteen days after the injection only a little larger than the sound testicle. "An accompanying psoriasis vulgaris shows no signs of disappearing." The other was an interstitial glossitis of two years' standing. Eight days after the injection the swelling diminished and the tongue could be easily moved. Ledermann reports a gummatous ulcer of the leg which was treated very successfully by Ehrlich's method.

Visceral Syphilis.—In cases of renal and hepatic syphilis the Ehrlich treatment can be profitably used. Alt recites a case of icteric syphilis cured after nine days, and Wechselmann one after seven. Lesser gives a case of lung syphilis accompanied with chronic nephritis in which the 606 gave brilliant results. Emery relates a case of grave stomachic syphilis relapsing in spite of mercurial treatment, which was successfully treated by 606. A case of syphilitic ulceration of the rectum is reported by Wechselmann, which rapidly healed, with slight consequent stenosis not embarrassing to defecation. It is thought that the treatment of visceral syphilis with 606 will very likely play an important part in the therapeutics of this disease. Up to the present visceral syphilis has been but little studied clinically. This is probably accounted for by the apparent rarity of the cases and the difficulty in observing and diagnosing them. Nowadays, after a positive or part positive seroreaction of Wassermann had been obtained, of course combined with a careful clinical examination of the patient, we can almost positively conclude that the trouble is syphilitic.

We must, however, keep in mind *that, when we have to do with nonsyphilitic visceral lesions concomitant with syphilis, the drug is contraindicated.*

Ocular Lesions.—There was an undoubted improvement in the cases seen by Emery of syphilitic conjunctivitis, choroiditis, and iritis; but he says the treatment was of too recent a date for one to appreciate definitely the results which appeared so excellent. Gluck reports a case of iritis with synechia, in which the photophobia disappeared on the second day after the injection and the eye became normal after eight days. A double iritis was cured three weeks after the injection of 606. The same observer cites a case of parenchymatous keratitis which cleared up two days after the injection of 606 and was notably improved but incompletely healed when the patient left the hospital twenty-one days after the injection. Wechselmann reports an optic neuritis appearing two months before 606 was injected. Since the injection the fundus oculi and vision have remained normal.

Syphilitic Lesions of the Nervous System.—Although Ehrlich himself has made the formal statement that the presence of certain lesions of the nervous system are contraindications for the administration of 606, nevertheless the drug has been employed in many nervous diseases consequent to syphilis. Wechselmann cites at least five cases (two of recent date) of syphilis of the central nervous system which underwent treatment with 606 without harmful results. A case of cerebral syphilis presenting a menacing gait was treated with 606 by Michaelis. The symptoms were soon reduced to headache. A case is reported of a woman with a long standing syphilis, where among other preataxic lesions there was a commencing optic atrophy. After the injection of 606 the opthalmologists who examined the eye said there was a considerable improvement in vision.

Alt gives a number of cases of epilepsy of syphilitic origin which were greatly benefited by the injection of 606. The attacks almost disappeared. Two cases of severe epilepsy with syphilis, which daily had four to five epileptic attacks and where the status epilepticus was so severe that death appeared imminent, were given an intravenous injection of 606 (for fear the pain of an intragluteal one would bring on a new status) with astonishing results. "In one case the seizures have quite disappeared; for five days none occurred."

The following reports of late syphilis which were treated with 606 are given by Dörr. Three paralytics were injected with insufficient quantities of the drug; accordingly, no effect could be expected. The patients who received 0.4 gram 606 were naturally improved. One patient who suffered from attacks of dizziness, paresthesia (one side), and diplopia was three weeks after the injection free from all these symptoms. Another suffered from dizziness, headache, disturbance in speaking and writing, and very marked disturbances in perception and conception. Four weeks after the injections of 606 the patient was less forgetful and suffered no longer from headache and dizziness Mattauscheck, who examined him, states that his powers of perception and conception were materially improved and that the disturbances in speaking and writing have disappeared. Wechselmann cites a case of testicular and brain syphilis which healed within fourteen days after an injection of 606.

Neisser reports the case of a woman with a syphilitic brain lesion (optic neuritis) following one

year after the initial lesion. There were choked disk, paralysis of several eye muscles, and terrible headache. The case was treated ineffectually with large doses of mercury and an appropriate amount of potassium iodide. After an injection of 0.3 gram in conjunction with the potassium iodide treatment all the subjective and objective symptoms declined with striking rapidity.

The Ehrlich-Hata preparation was used by Alt in a number of relatively recent cases of tabes. In six cases not only the subjective but the objective symptoms subsided and hand in hand with this there was a general improvement and the patients took on weight.

The fact that Ehrlich himself forbids the use of the drug in cases of syphilis of the nervous system, combined with some recent bad results following its use there, should force one to show very great reserve in treating such cases with 606. Fraenkel and Grouven have reported a death ensuing two hours after an intravenous dose of 0.4 gram. The patient was a young man suffering from a cerebral gumma. Ehrlich absolutely forbade Emery to use 606 upon a case of syphilis of the central nervous system which developed less than eight months after the infection and in which mercury had only given partial results. It is necessary to be very cautious until experience shows what forms and localizations of syphilis of the nervous system we can treat by the Ehrlich-Hata preparation. Of course, it is different with the tabetic patients at the beginning of their trouble, who still have their ocular integrity and appear much benefited by the treatment.

Hereditary Syphilis.—Pregnant women have received an injection of 606 without ill results. Gluck, however, speaks of a case where the heart beats of the fetus ceased a short time after the injection of 606. Michaelis injected a nursing child which was literally covered with a pemphigus syphilide with 0.1 gram. From the day of the injection it gained in weight and the cutaneous and buccal lesions began to disappear. Wechselmann injected with 606 a nursing child who had a large papular and pemphigus eruption, which was shortly cured. The positive Wassermann reaction disappeared and the child remained well.

Michaelis tells of a syphilitic child with an exanthem, an infiltration of the palms of the hands and soles of the feet, upon whom the lesions began to heal three days after and had entirely disappeared eight days after the injection of 606. A coryza persisted, however.

Two nurslings, according to Wechselmann, with pemphigus neonatorum were cured after the injection. Three others with the same disease died a few days after 606 was injected. The skin lesions indeed began to get better, but anemia, fever, and, in one case, opisthotonus appeared and death resulted. The section showed, in the first case, most extensive miliary gummata of the liver; in the second, gummata of the heart; in the third, pedatrophy. There were no signs of arsenic poisoning.

Wechselmann considers only those children whose nutrition is faultless are fitted to be treated by the new method. He holds that it is possible through the rapid dissolving of the large number of spirochetes by the administration of 606 to set free such an amount of endotoxin that thereby a transient damaging agent enters which the weak infant's organization cannot stand.

Ehrlich has stated that nursing children should not be given more than 0.03 to 0.05 gram of his preparation. He considers even this dose as lethal for some; for it was found that the syphilitic lesions of the nursing child were completely cured through the milk of the mother, who had already received an injection of 606. Ehrlich maintains that recourse should be had for some time to the action of the mother's milk before the child is injected with 606. Schreiber reports that the infants of two pregnant syphilitic women who were injected with 606 previous to the birth of their children showed no evidence of syphilis.

Relapses.—Wechselmann had not seen any relapses up to the time his paper was published, nor has Emery seen any in the various clinics he visited; yet various experimenters have observed them.

Géronne and Huggenberg, in their last report of twenty cases which were treated by 606 with good results, say they had five relapses. They observed the cases for thirteen weeks. Among these cases "there were two men who received an intramuscular injection (606). The clinical symptoms strikingly diminished, the Wassermann was soon negative and remained so, and then, after seven or eight weeks, on the site where the chancre was there appeared a new erosion in which the spirochetes were found. They conjecture that in the upper layers of the epithelium the spirochetes remain alive because the drug has not reached them. They intend in the future to treat the primary lesion, etc., locally. The two following cases are also reported by them. A case of specific laryngitis treated with 606 (the Wassermann was not negative) reappeared five weeks later. Another case of specific laryngitis was treated with 606. Wassermann became negative and remained so some weeks. After eight weeks it again became positive, but no clinical manifestations appeared. Neisser explains the relapses noted by the fact that too small doses (up to 0.4 gram) of the drug were used.

The relapses explain themselves, according to Wechselmann, by the fact that the spirochete is not a parasite of the blood, like the trypanosome, except in a very transient way; that it leaves the blood, enters the lymph spaces, and forms what might be called sorts of isolated centers in different parts of the body and that it is possible for the organisms in these foci to wake up and become virulent at periods more or less remote. Not only are the various relapses accounted for in this way, but the negative Wassermann reactions followed at variable intervals by the positive Wassermann reactions are also explained.

Failures with 606.—No failures were reported to Emery from the several clinics he visited. He saw in Lesser's clinic a syphilitic ulceration of the head and face in which no modification appeared ten days after the injection of 606. It was thought that the drug became encysted, so to speak, at the site of the injection, where a tumor persisted for some time, and therefore the 606 was not properly absorbed. It is to avoid such a condition that Michaelis recommends massaging the site of injection for at least ten minutes after the drug is administered. Ehrlich told Emery of a case in which he attributed the tardy healing to a previous administration of arsenic.

As to how the 606 medication compares with the mercurial (excepting, of course, the treatment of parasyphilides in which the drug has partially failed

and for which it was originally not intended) the following expressions of opinion are given:

"In most of the cases the syphilitic manifestations declined faster with 606 than with any other remedy used by us." (Pick.)

"In all the cases where the time of observation is long enough there was a decrease of the manifest symptoms; indeed, the improvement was mostly a striking and quick one." (Géronne and Huggenberg).

The instantaneous result of 606 was "almost dumfounding; whether a lasting cure (the absence of relapses) has been accomplished or whether this can be accomplished with greater doses we will report next winter. I would like to call your attention to the fact that forms refractory to mercury which had been for years in a stationary condition improve strikingly and quickly after the injection of 606" (Dörr). "Regarding the specific character of the remedy no doubt can prevail" (Neisser). He is also quoted elsewhere. Speaking of his cures, Kromayer says "on the whole I did not think it possible."

"It is obvious that after so short a time we cannot say whether a final cure of lues is brought about by the new remedy. Experience will teach this. I believe there is no longer any doubt (I have more than 150 cases on hand) that so effective a specific remedy as the Ehrlich preparation has not existed till now" (Alt).

"Sceptical criticism can no longer exist. The new preparation affects the symptoms of syphilis in their infectious forms with a rapidity and thoroughness that no former drug had in any way approached. The healing is so rapid that one cannot exhibit the patients because most of them show nothing after a few days and leave the hospital" (Wechselmann). (He tried the drug on eighty cases.)

Prophylaxis.—On account of an action so constant, rapid, and durable, upon the mucus patches and all erosive and ulcerous lesions whence the infection takes place, 606 will play a prominent part in the contest against syphilis. Thanks to the Wassermann reaction and 606 it may be possible quickly to "sterilize" partially or entirely all those infected with syphilis.

The appearance of some form of latent syphilis entailing an injection of 606 will assure at least for a considerable time an innocuousness. At present protective measures are unfortunately often too late and on account of the frequency of application therapeutic interventions are difficult.

For those syphilitics who have not conformed strictly to the mercurial treatment and whom we cannot forbid marrying because their disease is old and they have had no lesions for a long time it would be well to advise as a measure of precaution and security an injection of 606 some months before marriage. With syphilitics desiring to marry we usually consider the frequency and intensity of their relapses, the character and duration of the treatment, the period over which the disease has extended, the time elapsed since their last manifestation, and finally the Wassermann reaction. Can we now tell them after the administration of 606 that they are cured and are fit to marry? We know the wonderful effect 606 has upon the lesions of syphilis and even the power it has of changing a Wassermann reaction from positive to negative. We might even legitimately stop all treatment after an injection of 606, provided the Wassermann reaction frequently repeated showed negative results. We cannot, however, lose sight of the fact that, at times, a negative Wassermann reaction has been coexistent with the manifestation of a tertiary lesion, and finally have we enough evidence of the definite action of 606?

Emery makes the following emphatic statement: "The complementary precaution of a mercurial treatment should in every case be exacted." With this statement we must at present agree. Ehrlich is not opposed to the consecutive or simultaneous use of 606 and mercury; he is, however, opposed to the synchronous use of 606 and other arsenical preparations.

The question is continually asked to-day, not only by the physician, but the layman as well: "Will 606 after a single injection definitely cure syphilis? It is this question which has caused the greatest confusion regarding the *real value* of Ehrlich's discovery. This confuson can be cleared up easily by reading Ehrlich's article, "Chemotherapie von Infektionskrankheiten." A certain number, very few perhaps, are certainly not cured by a single injection of 606, as is attested by the relapses reported and where a second injection is necessary. We can readily understand the possibility of some of the spirochetes escaping destruction either by the fact that the dose of the drug was too small or that they might have scattered themselves in such places in the body where a single injection could not reach them.

We must remember that Ehrlich says that the dose of the drug can be learned only by slow and patient observation. We know positively that 606 has shown itself superior to any other mode of treatment so far as its action upon a large number of syphilitic lesions is concerned. It has been said we must discriminate between the action of 606 upon the lesions and its action upon the evolution of the disease (the clinical development of syphilis), that is, the syphilitic infection itself. The clinical development of the disease is determined by the parasites, in that they hinder the curative reaction of the cells of the organism.

The lesions, of course, are the consequence of the infection and the obvious lesions in almost every case rapidly disappear after the injection. This fact accompanied by the appearance of a negative Wassermann reaction three weeks to two months after the injection of 606, together with the early disappearance of the spirochetes in lesions before the healing process begins, and probably the appearance of the Herxheimer reaction, which appears about the same time the spirochetes disappear from the other lesions, combined with the results of animal experimentation, are most convincing proofs of the high parasitotropic value and great sterilizing power of 606.

"How can we prove," says Emery, "this action quasi miraculous, which we see with our eyes, which we believe perfectly realizable, but which we still only catch a glimpse of?" In order to demonstrate that a definite cure is produced by 606 we must dispose of the following facts: (1) The presence or absence of the spirochetes in the lesions. (2) The presence of a positive, part positive, or negative Wassermann reaction. (3) The results of experimentation upon animals. (4) The results of a study of the clinical developments of the disease.

The first of these facts is proved in many lesions. The second is proved in the greater percentage of cases. Some consider it so in all. Regarding the

third, it may be said that experimentation upon animals is open to some objections, in that it is so much more difficult to generalize in them the infection than in man. The following report quoted from Neisser is of no small value as bearing upon this subject:

Of twelve syphilitic apes which were treated by intramuscular injections of 0.025 gram 606 per kilo and by intravenous 0.015 gram per kilo only three of these were surely healed at the time he published his article; two possibly and the other seven were certainly at that time not cured. With two of the apes, which were given an intramuscular injection (0.25 gram) of 606 eleven days before they were infected with syphilis, the primary lesion appeared very much later and was much less extensive than with the apes who had been simultaneously infected and who had not received a previous injection of 606. It is further reported that Neisser has succeeded in reinfecting syphilitic apes cured by 606. As for the fourth fact *only time will show.*

In answer to the question: Is a definite cure brought about by the injection of 606? Emery answers as follows: Yes, in the majority of cases. But who has not seen syphilis, unknown or ignored, consequently not treated, craftily disappear during the first stages of its development and remain mute during periods of ten, twenty, thirty years and even during a generation, wake up in the aspect of a grave disease of the nervous system—general paralysis?

Indications — Contraindications. — The patient should be carefully examined with a view of ascertaining the presence of lesions other than syphilis.

As we know the toxic effect of the arsenical preparations, and especially their injurious action on the optic nerve, Spatz insists that in every case we intend to treat with 606 we must previously examine the fundus oculi and accept for treatment only those who have a normal fundus. Before an injection of 606 is given an examination of the blood should be made in order to ascertain by the Wassermann method what the seroreaction is. Spirochetes should be looked for in the chancre, the examination being made according to Burri's method or, better possibly, with the dark field illuminating apparatus or both methods. The temperature and body weight should be taken and the urine examined (especially for albumin). *If the form of the disease is appropriate then and then only should we give an injection of 606.*

According to Blaschko the contraindications are: old age, affections other than syphilis of the kidney, heart, liver, spleen, lung, blood-vessels, such as an advanced aneurysm, and particularly those who have not a normal fundus oculi; with those who are suffering from a grave syphilitic affection of the brain, such as recent hemiplegia or an acute or subacute meningitis, 606 should be used with the greatest caution and only after the physician is thoroughly convinced that the treatment with mercury is not efficacious. Cachexia or a weak constitution is not always a contraindication.

The method of Ehrlich is indicated (Blaschko): (1) In all cases where the lesions are refractory to mercury. (2) In a relapse immediately following a so-called mercury cure. (3) In cases where there are continual relapses. (4) When there is an idiosyncrasy toward the mercury medication. (5) With all cases of malignant syphilis with secondary and tertiary syphilides which are destructive or dangerous on account of their site and the disorders they occasion. (6) To make the first attack on the disease with this drug at the appearance of the chancre and at the same time treat the initial lesion locally followed by a prolonged and intermittent treatment.

In all other cases we can treat the lesion independently either by Ehrlich's or the mercury method, as occasion and convenience present themselves. Not a few syphilographers think that these two modes of treatment in a certain number of cases, instead of excluding one, can complete and supplement each other. A long comparative study of the two medications as to their advantages, propriety, and efficacy will doubtles permit us to narrow the precise indications of the one or other.

Whatever may be the future of the Ehrlich-Hata preparation, and now there is no doubt regarding it, the admiration of the entire world must go out to the man who bestowed it, who gave us the Ehrlich side-chain theory, the Ehrlich granules in the leucocytes, who proved that there are chemical substances which are fixed by microorganisms living in our body, and now—to crown it all—conceives the *therapia sterilisans magna* which gives the *coup de massue* to syphilis almost at the moment of its inception.

CUSTODIANSHIP OF THE WATCH AND BIBLE OF DR. BENJAMIN RUSH.*

WITH BIOGRAPHICAL NOTES.

By ROBERT ABBE, M.D.,

NEW YORK

Few more interesting souvenirs could come into the keeping of the profession than the two typical possessions of Dr. Benjamin Rush—so full of character—as his watch and his bible. He was a man of such rich experience, rare character, and notable attainments, that he made a lasting impression on his time both in professional and patriotic fields.

The old inscription of the former owners of the watch, namely,

BENJAMIN RUSH, M.D.
Sig. Dec. Ind.
Ob. 1813
RICHARD RUSH.
Ob. 1859
BENJAMIN RUSH

*Read at a meeting of the Practitioners' Society, October 14, 1910.

gives it a personality of its own. One feels something of a thrill as one holds it in his hand and thinks of the hand that held it long ago at the death bedside of many great heroes of revolutionary days, or when keeping appointments with the early presidents, the highest statesmen, Franklin, Humboldt, and a host of others.

A little later it followed the fortunes of Richard Rush, the son, equally great in the annals of the day, as attorney general of the United States, and later our minister to England and to France. This watch was often at the court of St. James, where the younger Rush figured well and became an important factor in establishing the Monroe Doctrine by writing a warning to our government of the secret understanding between European monarchs to thwart the spread of republican ideas which were taking root in America. From his letters extracts were used by President Monroe in his message to Congress devising the Monroe Doctrine. It also figured in France where Richard Rush as our minister was the first to recognize the Republic in 1848.

I have been asked to bequeath this souvenir to the most distinguished member of our profession, whom I consider to represent the spirit and quali-

ties eminent in Dr. Rush, and by him to be passed on to successive custodians as years go by. Thus it is believed it will be a mark of distinction to be one of a chain of honored names perpetuating the just renown of Rush. We have in our country none too much of the oriental "ancestor-worship." We may well keep alive the names of good men.

In seeking a name for the first custodian I have, by elimination, chosen one whom I think you will agree with me has added to scientific research, an untiring spirit of work, a broad human helpfulness, patriotism, and literary culture—Dr. Weir Mitchell. It is specially fitting that Dr. Mitchell is a Philadelphian and an ex-president of the College of Physicians of which Dr. Rush was a founder. Dr. Mitchell agrees with me that the idea of perpetuating this memorial is most happy, and he accepts the trust, and agrees to nominate a successor, and to have the watch preserved in the cabinet of the institution as one of its most valuable assets.

As a companion piece to be kept with the watch, I have had made a book of blank pages finely bound, in which I have written the following brief biographical statement as representing the estimate of one of the profession in New York, followed by one from the pen of Dr. Weir Mitchell of his own city. Following this is a collection of photographs and engravings of all the existing portraits of Dr. Rush, with such autograph letters as I could obtain. Then comes the letter presenting the watch and inaugurating the scheme by the lady from whose hands it came to me. On succeeding pages are portraits of successive custodians of the watch, assigning perhaps the essential reasons of choice as well as of the acceptance of the trust.

Thus in time there will be a most valued series of portraits and autographs of noted medical men and the custodianship of the watch will be a sort of blue ribbon.

The name of Dr. Benjamin Rush has outlived the century of his birth and, by general concession, a century and a half later, stands on the roll of the medical profession the most noteworthy in our country's history.

The traits of character and qualities of mind which brought him to this commanding eminence may wisely be kept before succeeding generations as worthy of admiration and emulation.

He was born in a century when the light of science was dawning; when the art of medicine was only emerging from the crude customs and practices of medieval darkness. Medical teaching

was as child's play compared to modern revelations.

He was among the earliest students to sail back to the old world and listen to the masters of English and French teaching after he had absorbed the limited training of our provincial schools. Organized science was not known. Men were gathering facts. The personal friendship of Franklin, the acquaintance of Humboldt and of many other distinguished men, inspired him. Rush followed this spirit of study and as he says, had "a habit of making everybody with whom he conversed contribute to his improvement." He was untiring in his work —insistent on meeting the most distinguished men in all professions wherever he went.

He habituated himself to the improvement of every hour of the day and contributed letters to the lay and medical press whenever stirred by popular questions. Drawn into political controversy when his country was disturbed, he sacrificed time and energy to correcting public abuses. He was fearless in differing with friends on topics of the day, displaying a rare independence of thought.

He joined the patriots of his time, when to be

a republican threatened his prosperity. He fought prerogatives of royalty and led in committees advocating separation from the mother country. He was called to represent his State in the first congress and signed the Declaration of Independence in the stirring days of the revolution.

He was the intimate of all the patriots and heroes of the early days of our country's peril. For many years he was trusted by General Washington, who gave him command of the medical and surgical work of the Continental army, but whom he afterwards criticized with fearlessness of results that won the President's disfavor. Staunch admiration for his sterling worth led President Adams to appoint him Director of the U. S. Mint in the face of forty competitors. This responsible office he held during the last twenty years of his life.

No greater tribute could be paid to any man than that in which President Adams speaks of him after his death in a letter to Elbridge Gerry, saying "As a man of science, letters, taste, sense, philosophy, patriotism, religion, morality, merit, usefulness, taken altogether, Rush has not left his equal in America, nor, that I know, in the world. In him is taken away, in a manner most sudden and unexpected, a main prop of my life." Allowing for the exaggerations of friendship, President Adams in those words attempted a portrayal of virtues which, in his mind, dominated the portraiture of the man.

Dr. Rush was a deeply religious man from his youth, first a Presbyterian, then after marriage an Episcopalian. His studious and thoughtful habits, his controversial mind, incessant work and fearless independence made him irascible and brought him enemies. Nevertheless, he sustained the largest practice in Philadelphia, mainly among the poor.

We must, for all time, respect the man whose great humanitarian impulses dominated every act of his life. The epidemic of yellow fever in 1793 brought out the type of man most clearly. Deeply pondering on the terrible ravages of the disease, which swept Philadelphia in midsummer and reduced it to a few thousand, left to brave the fight, Rush remained among them, defying the disease, and putting in practice his best wisdom, though his methods differed from those of most of the faculty.

In retrospect, modern research shows that his opponents were more in the right than he in ascribing the epidemic to specific causes brought from without to the city, while he insisted it was from the unsanitary condition of the city only.

Rush was proud of his own calling and always ardent in the defence of the right as he saw it. We see the spirit of independence germinating in the grandfather who was a captain in Cromwell's army, came over with William Penn, and founded the stock from which Benjamin Rush was born in Philadelphia in 1745.

Of his medical writings some were controversial, some instructive, but more remarkable than all was his work on insanity, which competent judges regard as a century ahead of his time.

Diagnostic Value of the Lipoids Excreted in the Urine and Sputum.—The so-called anisotropic "liquid crystals" sometimes found in these excreta doubtless represent a mixture of fat and albumin. While we know little of their chemical constitution, their presence, as revealed by the polarisation microscope, should possess diagnostic value.—*Deutsche medizinische Wochenschrift.*

COMPLETE SUBPARIETAL RUPTURE OF THE KIDNEY, WITH REPORT OF A CASE.

By HENRY G. BUGBEE, M.D.,

NEW YORK.

The extreme rarity of this injury, the vagueness of the signs and symptoms, with the probability that many cases are never diagnosed, or when recognized are placed upon proper treatment when too late, leads me to review the condition and report this case.

In few of the monographs on this subject, or even in the textbooks, is any attempt made to divide the cases into groups according to the extent of the lesion, hence it is impossible to give the proportion of the cases in which the lesion was complete. All ruptures, of whatever degree, are rare, as shown by the following statistics: In 2,610 post-mortem examinations in the course of ten years at the Middlesex Hospital there were 12 instances of subparietal rupture of the kidney, of all degrees. Goldstein reports 23 cases in 20 years at the Friedrichshain Hospital. Watson found 27 cases recorded at the Boston City Hospital in 14 years. He collected 603 cases recorded to 1903. In another series of 13,455 autopsies there were 31 instances of kidney rupture (Morris and Herzog). Johnson, in his report of all kidney lesions treated at the Roosevelt Hospital from 1890 to 1898, found one case of complete rupture of the organ. Brewer in a series of 140 cases of surgical kidney had one case of complete rupture.

Inasmuch as a very slight laceration of the kidney causes a relief of tension, it is probable that few ruptures are complete.

Injuries of the kidney occur more frequently in men. This relative frequency is probably due to their exposure to injury, but is also attributed, by Küster, to the fact that injury more commonly produces movable kidney in women. Thus he found of 306 cases of subparietal ruptures of the kidney, that 281 were in men. Complete rupture of the kidney may result from direct or indirect violence. The former is more common, and, as in the writer's case, the force is severe. Falls upon the feet or buttocks have produced the lesion, and Watson reports a case in which muscular exertion was the exciting cause. The ribs, by crushing the kidney against the spine, may assist in the production of the lesion. Hydraulic pressure, acting through the blood-vessels and the distended pelvis, is thought by Küster to play an important rôle. The organ distended with urine is certainly more prone to rupture. The right kidney is more frequently the seat of lesion than the left (242 of 272, Morris).

Pathology.—In complete rupture of the kidney one pole may be separated from the remainder of the organ, or the laceration may extend through the pelvis of the kidney and even into the vessels, as in the writer's case. The kidney usually ruptures in a horizontal direction, in the interlobular lines of the embryonic kidney. Although the rupture is complete, should it not involve a calix or the pelvis of the organ, urinary extravasation does not take place at once. Hemorrhage of more or less severity is immediate. If the fatty capsule is not torn, a hematoma rapidly forms beneath it. Pressure of the surrounding organs, also of the peritoneum, tends to check it. When the laceration involves the kidney pelvis, hemorrhage is more severe, and

an extravasation of blood may fill the loin. The peritoneum is protected by the fatty capsule interposed between it and the kidney, yet it may be torn, allowing a rapid extravasation of blood into the peritoneal cavity. Often other viscera are injured, most commonly the liver and spleen. Fractures are not infrequent complications. Suppuration rapidly ensues, should the patient withstand the primary shock, when a complete rupture is treated expectantly.

Symptoms.—The history is usually that of a severe crushing blow in the side, followed by pain, symptoms of shock, and internal hemorrhage. Hematuria is present unless the renal artery or the ureter is plugged with blood clot, or a complete destruction of the kidney has taken place. A tumor may rapidly fill the loin of the injured side. This tumor is tender, often irregular in contour, is due to perirenal extravasation of blood and urine,

and may rapidly increase in size (from a secondary hemorrhage); or may disappear altogether (from a dislodgment of a clot in the ureter). An absence of the tumor indicates a rupture of the peritoneum, with extravasation into the peritoneal cavity. Peritonitis may follow this, but Tuffier has shown that in single introductions of urine into this cavity, when made gradually, or when sufficient time is allowed to elapse between introductions, peritonitis does not result. Vomiting is often immediate. Rigidity of the abdominal muscles and ecchymosis may be noted. Anuria may take place immediately after the receipt of the injury, and is due to extensive laceration of the kidney with reflex inhibition of function in the other kidney; to injury of both kidneys; a plugging of the ureter; laceration of the renal vessels; or rupture of a fused kidney. Often it is of short duration (12 to 24 hours). Symptoms of suppuration follow these extensive ruptures if operative treatment is not employed at once.

Diagnosis.—The patient will, as a rule, give a history of having received a severe blow in the side. The examination reveals a tumor in the loin. There is, as a rule, hematuria. The patient is in a state of profound shock. These symptoms with evidences of internal hemorrhage should lead one to treat the patient for rupture of the kidney.

Prognosis.—This depends upon the delay in applying the proper treatment. The primary mortality is due to hemorrhage, while secondary deaths are caused by infection, which may be hematogenous or ascending in origin. The mortality of all cases of subparietal ruptures of the kidney has been estimated at from 32 to 92 per cent.

Treatment.—This resolves itself into expectant and radical. Expectant treatment should be employed only as a temporary procedure, to allow the patient to recover from the primary shock. The patient should be watched very closely, and this line of treatment must be immediately superseded by operation if the hemorrhage is progressive, or where there is reason to believe that there exists a rupture of the peritoneum with intraperitoneal complications. Expectant treatment consists in rest, application of cold and pressure to control the hemorrhage, treatment of the shock, with a refilling of the depleted vascular system. Operation is indicated in the vast majority of cases, and should be immediate. The choice of the operation depends upon the presence or absence of complications. When intraperitoneal organs are injured the abdomen should be opened anteriorly along the linea semilunaris. In uncomplicated cases the posterior incision, along the outer border of the erectorspinæ, and quadratus lumborum muscles, or the oblique incision parallel to the free border of of the ribs is preferable.

The steps of the operative procedure should lead to the checking of the hemorrhage, removal of the kidney if necessary, and drainage of the wound. Associated lesions, when found, must be treated. Manipulation should be reduced to a minimum, and the operation should be performed as rapidly as possible.

The case which I wish to report is as follows: Patient R. O., aged 15. Family history negative. Past history: Ordinary diseases of childhood, otherwise, negative. Present illness: On February 19, 1910, while coasting downhill, his sled turned, throwing him violently against an iron post. The blow was received squarely between the ribs and the crest of the ilium. Immediately he passed into a state of collapse, was carried home, and seen by a physician who stated that he was unable to find any evidences of severe injury and expressed the opinion that the boy would be all right in a few days. His mother states that he became very pale and cold, and complained of pain in his side. Two hours after the accident he voided an ounce of bright, bloody urine. One hour later, another small quantity of the same character was passed. He was now seen by a second physician, who advised his immediate removal. He was placed under my care at the Vassar Bros.' Hospital, in Poughkeepsie, nine hours after the accident. Physical examination on admission: A boy of medium frame, fairly well nourished; extremely pale; surface of the body covered with a clammy sweat; pupils dilated and sluggish; respirations slow and gasping;

pulse thready, weak, and irregular; temperature 97°. The right side of the abdomen was filled with a rather firm, rounded, slightly movable, tender mass. The remainder of the abdomen was slightly distended, tender, and rigid on the right side. Rectal examination negative. I made the diagnosis of probable rupture of the right kidney, with extensive hemorrhage. Owing to the exceedingly poor condition of the patient, it seemed best to apply palliative measures, in the hope that he would rally sufficiently from the shock to render the operation a less grave procedure. He was placed in bed; pressure and cold applied to the abdomen; salines administered per rectum, and morphine (grain ⅛) given. After watching the patient closely for ten hours, with little improvement in the general condition, I decided to operate without further delay. An intravenous infusion of 400 c.c. of saline solution was administered and a rapid exploration of the right kidney made. The posterior vertical incision was made along the outer border of the erectorspinæ muscle and the mass exposed. The mass filled the loin, extending above the free border of the ribs, and below to the crest of the ilium. Lying posterior to the peritoneum, it consisted of a completely ruptured kidney (as shown in cut), and blood clot. The whole mass was surrounded with fluid blood and urine. The pedicle was rapidly ligated and the kidney removed. Exploration revealed no injury of the peritoneum. The wound was packed, the bladder catheterized, four ounces of urine and blood were evacuated, and the patient returned to bed. The pulse, which was scarcely perceptible at the wrist, when the patient was placed upon the operating table, improved with the infusion, and remained strong throughout the operation, which lasted twelve minutes. Following the operation the patient's condition rapidly improved. Salines per rectum, and a second intravenous infusion of 400 c.c. were given. From this time on recovery was uneventful and complete. The first few days after the operation albumin and casts were found in the urine. On the fourth day the urine became normal, and has remained so ever since. The amount of urine has averaged 35 ounces a day. The patient left the hospital cured six weeks after the accident.

40 East Forty-first Street.

THE NONENTITY OF ACUTE DILATATION OF THE STOMACH.

By GEORGE EDWARD BARNES, B.A., M.D.,

HERKIMER, N. Y.

In the index of diseases of the stomach is mentioned acute dilatation. Although cases of it are very infrequently reported, it is considered by the profession generally and even by gastrologists to be a real condition. I, however, have never been able to convince myself of its existence. I cannot comprehend how a muscular organ like the stomach can suddenly dilate to large proportions. In the living body there is no sufficiently distending force to overcome quickly the accustomed and prevailing strength of the gastric musculature. Such great atony and stretching as is supposed to exist could hardly be produced so acutely. It seems to me that in cases of supposed acute dilatation the dilatation is chronic and the symptoms are produced chiefly by other conditions, usually an intestinal stenosis or obstruction. The multiplicity of the assigned causes of this supposed disease is itself significant of error.

Boas recognizes acute dilatation or paresis as a real entity but states that at the present time no decisive view on the etiology of the recorded cases can be reached. He suggests that not enough attention has been given to deflections of the duodenum as a possible cause of the condition. He classifies seven causes of acute dilatation and says that the most characteristic cases are due to mechanical kinking. He specifies kinking of the pylorus or the jejunum, acute obstruction of the pylorus by gallstones, torsion of the mesentery and compression of the duodenojejunal section by the superior mesenteric artery. I agree that these conditions would cause symptoms, but I cannot see how and he does not state how they could cause acute dilatation of the stomach. They could hardly operate through nervous reaction or by damming the stomach contents, which could be thrown off by vomiting.

Indiscretions in diet are considered to be the most frequent cause of acute dilatation. Riegel states that many of the patients have stomach trouble or are reduced by anemia or some other disease before they have the acute dilatation, that the disease may be mild or severe, and that slight degrees of acute atony are probably more frequent than we suspect. He also states, "While it is true that in these cases of acute insufficiency and dilatation indiscretions of diet are the direct cause, it seems difficult to understand why such very severe forms are rare, as great indiscretions are undoubtedly frequently committed." Now he and other clinicians concede that some of these cases have a history of pre-existing stomach trouble and, although the cases, of course, had not been previously examined, it is fairly certain that the patients had chronic dilatation. It is also almost as certain that other cases reduced by anemia or other diseases had also chronic dilatation before they had the supposed attack of acute dilatation. Patients with chronic dilatation are prone to have also anemia and other chronic diseases, especially of the involuntary muscles. The mild cases of acute dilatation following indiscretions are probably only cases of acute disturbance of digestive functions coincident with and sometimes referable to the chronic dilatation. Some stenosis or obstruction may also occur. Our patient was in the habit of overeating. After eating a large quantity of green peas she had nausea and vomiting, continuing for two days, *i. e.* indigestion or acute dyspepsia. On the third day the patient was unable to vomit and was in a state of collapse. The doctor, called on that day to see the case, found on examination that the stomach was very much dilated. Such finding, however, does not at all prove that the dilatation did not antedate this acute sickness. The doctor aspirated from the stomach a liter of brownish fluid and some of the undigested green peas. The quantity and color of the fluid can be accounted for in several ways and is consistent with an obstruction, and the presence of the green peas was an indication, perhaps, of an obstruction and certainly of gastric insufficiency which was neither necessarily nor probably acute. The case gradually improved. Six weeks later patient had another attack from which she recovered. Riegel says that a suggestive feature of this and some other cases is the absence of vomiting in the advanced stage of the disease and that this can be explained only by the weakness of the stomach resulting from excessive distention of its walls, or because paralysis of the musculature had become complete. But it must be evident that absence of vomiting was due to the very

weak condition of the patients. Moreover, it is believed that no weakened condition or paralysis of the musculature can prevent vomiting. There can be in such a case as this no acute overdistention of the stomach. Green peas certainly did not dilate the stomach. Nothing—neither air, water, nor food—was being forcibly pumped into it and stretching it. Pain does not appear to be a symptom in the mildest cases. But it is most improbable that an acute dilatation could occur without producing severe pain.

The more severe cases of acute dilatation following dietary indiscretions are said to represent a more serious sickness and some of them are said to end fatally. In these cases I think that the chief symptoms and the fatal issue are caused by an acute intestinal stenosis or obstruction and that the dilatation is an old condition. But I also think that symptoms of acute indigestion due to the chronic dilatation may cause the kinking of the intestine which produces the obstruction. Patients with chronic dilatation often have attacks of acute indigestion due to stasis, and experience severe vomiting. During the churning of the intestines by the diaphragm and abdominal muscles in the act of vomiting, especially when the intestinal walls are also atonic and flabby, a coil may be thrown about so as to produce a valvulus or kink, particularly at the duodenojejunal angle where one end of the coil would have a fixed point of attachment and a predisposing dent would be made anteriorly by the superior mesenteric artery which itself would act as a fulcrum. When such a kink is found at autopsy the conclusion is jumped at that it caused the gastric dilatation, whereas the reverse relation indirectly is really more logical.

Acute dilatation is said to develop after laparotomies. Riegel says that it seems clear that most of the cases of postoperative dilatation so far reported are secondary to occlusion of the duodenum or some other portion of the intestine, resulting from pressure by cicatricial bands, or some other event connected with the operation or with the preceding disease. It is most probable that there are cases of intestinal obstruction arising from injuries received during operation, and I think that the dilatation is not the result of such obstruction, but a pre-existing condition. The occluded point, however, would probably be below the duodenum. Extensive or careless handling of intestines during operation may indeed produce a volvulus or kink which would cause obstruction both in patients with and without chronic dilatation.

A similar statement may be made about cases of supposed acute dilatation following acute peritonitis. Peritonitis, however, if extremely severe, might cause temporary paralysis of gastric musculature and possibly some acute dilatation. There have been reported three cases of supposed acute dilatation following peritonitis after abdominal operations. One of these, for instance, followed an operation for incarcerated hernia. But I am inclined to think that the symptoms were due to the condition of the incarcerated gut and that the dilatation was pre-existent and coincident. The field of operation in cases of this kind is so remote from the stomach that a consequent peritonitis would not be apt to involve the organ unless the infection is general and severe. Kinks might be produced during operation in these cases as well as in those not followed by peritonitis.

Again, traumata of the abdomen probably do not cause acute dilatation, but may cause kinks from irregular peristalsis, peritonitis which produces bands, clefts, or fenestra in the mesentery or omentum, and local contusion, all of which resulting conditions may cause acute stenosis or obstruction in patients with as well as without a chronic gastric dilatation. If on autopsy of a patient who has died from a blow in the epigastrium or elsewhere a dilatation is found it need not be concluded that the blow caused the dilatation and that the dilatation caused death.

A case is reported in which, it is claimed, characteristic acute dilatation was caused by scarlatina during convalescence. It is inconceivable how scarlatina during convalescence or any other period could cause acute dilatation. The case is typical of acute intestinal obstruction terminating in death, the dilatation being a chronic and coincident condition.

It is likewise inconceivable how certain chronic diseases could cause acute dilatation. As already stated, patients with chronic diseases are probably more apt to have in general weak involuntary muscles. But this condition would permit a chronic and not produce an acute dilatation and would predispose to intestinal obstruction.

Emotions affect the peristalsis of the stomach, but it is beyond imagination how violent emotional disturbances could produce acute dilatation. It is possible that much violent weeping, like vomiting, could cause a kink of the upper jejunum. Prolonged emotional disturbance might be in part a cause of chronic dilatation only. Strange as it may seem on first thought, no relation can be seen between central lesions and acute dilatation.

Anesthesia is supposed to cause acute dilatation, but it is past recognition how it could either by central, local or general action. Such cases are probably the same as those called postoperative, which have already been mentioned.

Epigastric hernias could not very well cause acute dilatation by tugging on the omentum or in any other way, but they could cause symptoms which might be wrongly referred to a dilatation which is chronic. Other internal hernias, notably into the duodenojejunal fossa, might also cause misinterpreted symptoms. The manifestation of hernias, too, is apt to be chronic rather than acute.

Acute parenchymatous gastritis could not cause acute dilatation for the musculature would not be involved.

One writer considers acute dilatation to be due to paralysis of gastric musculature or spasmodic contraction of the pylorus. But, as has been already intimated, nothing short of crushing and stretching of the musculature could cause acute dilatation, and such causes do not exist. According to present knowledge, as also already stated, destruction of the nerves innervating the stomach would not cause acute dilatation. It is a mechanical impossibility that spasmodic contraction of the pylorus should cause acute dilatation. This author says that the cause of death is difficult to state, but that it may be autointoxication or some direct injury of the vagus nerve. Such a virulent autointoxication is unknown, and no injury to the vagus could cause death as a result of acute dilatation, even if the latter condition ever occurred.

But few autopsies have been made on these cases of so-called acute dilatation, but in a part of them an obstruction has been found at the duodenojejunal juncture. An obstruction in the upper intestine might easily be overlooked or obliterated in post-mortem manipulation. Varying degrees of ob-

struction at this predisposed point would account for the symptoms in the majority of cases, but the dilatation would be a chronic pre-existing condition.

It is possible that in some cases of so-called acute gastric dilatation the symptoms may be produced by some functional disturbance of the duodenum (instead of indigestion or intestinal stenosis or obstruction), the dilatation, however, being chronic.

REPORT OF TWO CASES OF TETANUS FOLLOWING VACCINATION.

By CLIVE D. SCOTT, M.D.,

ST. LOUIS, MO.,

CHIEF DISPENSARY PHYSICIAN FOR THE HOSPITAL DEPARTMENT, ST. LOUIS, MO.

The alleged disastrous effects of vaccination is a subject concerning which so much has been written that it might seem, in view of the beneficent effects of this operation, a work of mistaken frankness to add to the body of literature anything which, with the remarkable ingenuity possessed by the fanatical antivaccinationist in distorting the statements of medical writers, might be seized upon as incontrovertible evidence for the support of his favorite theme. Yet, notwithstanding this unfortunate propensity, it is the belief of the writer that the best interests of the medical sciences are subserved by exact statements of the facts in these cases, as in others; for in the past the lack of exact data is to a considerable extent responsible for the misdirected enthusiasm of the antivaccinationist to-day.

The following two cases of tetanus occurring in children recently vaccinated came under my observation during the fall of 1909, incidental to the annual campaign of vaccination prosecuted under my supervision, by the Health Department of St. Louis.

Case I.—E. D. F.; white; male; aet., six; nativity, St. Louis; a pupil of one of the public school kindergartens, was vaccinated (primary) on November 1, 1909, by a vaccine physician of the Health Department, in the customary manner and with one of the standard viruses prepared in this country, under the supervision of the Public Health and Marine Hospital Service, and which was received from the laboratory about three days previously. Upon the same day on which this child was vaccinated 117 other children in the same school and 48 additional children in other schools in the city were vaccinated with a virus procured from the same dealer and of the same consignment, making a total of 165. The operation in all of these cases was performed in the usual manner adopted by the Department, as described below, and by a physician of large experience in this work, in whose experience no unfortunate result had previously occurred. With respect to this particular child, the evolution of the vaccine lesion was uneventful, the successive stages of its development being as is normally observed. During the course of the progress of this lesion, the family, of which he was the only child, went through the domestic ordeal of "moving," the affected arm of the child being dressed, from time to time, by members of the family. Some days after the vesicle had begun to dessicate, and after the family had become settled in their new home it was observed by the mother that the child was not feeling quite well. This state of ill-being continued for a day or two, various symptoms of discomfort being manifested, and on the morning of Sunday, Novermer 21, after a restless night, the child was seized with a sudden and severe convulsion, which so alarmed the parents that they at once called in their family physician, Dr. E. H. Johnson of this city, who, after a careful examination of the patient, pronounced it as suffering from tetanus. Dr. Johnson at once communicated his diagnosis to the Health Department, and upon this information all vaccine virus on hand was at once called in and vaccinations temporarily suspended. The local depot of the firm from which the virus was obtained was at once notified of the occurrence and was requested to submit samples of the strain of vaccine issued the Department for use on Nov. 1. This request, unfortunately, could not be complied with, for the reason that no records of the laboratory numbers of vaccines had been kept by the depot in question. As a consequence of this and from the fact that all of this supply on hand had been exhausted, it was impossible to obtain a specimen for experimental purposes. In order to obviate any further possible bad results, in the event we had been dealing with a contaminated product, all vaccine on hand was returned to the dealer and a fresh stock was had from another laboratory. The condition of the child's arm at this time presented nothing of an unusual character to the eye, the inflammatory reaction being of moderate degree, and the remains of the crust being still present. The state of the patient became rapidly worse during the day and night following the initial convulsion, all the classic symptoms of a severe tetanus being well developed, and, despite a very active treatment by means of antitetanic serum and other well-advised measures, on the morning of Monday, November 22, the patient died.

Case II.—R. D. J.; white; male; aet., seven; nativity, St. Louis; a pupil of the public schools, was vaccinated (primary) on November 5, 1909, by a vaccine physician of the Health Department, with a virus prepared by the same firm which supplied that used in the case recorded above, and received from the laboratory a few days later than the consignment mentioned in connection with that case. Upon the same day on which this child was vaccinated 103 other children were vaccinated in the same school, and in other schools in the city 72 additional children were vaccinated with virus procured from the same house and of the same consignment, making a total of 175. The operation was performed in the usual manner and by the same physician who vaccinated the child mentioned above. The evolution of the lesion was orderly and resulted in a well-formed vesicle, with moderate inflammatory reaction. During the course of its evolution the child was attending school and at odd times playing about as usual, portions of his time being spent at the home of a relative nearby, a teamster, who had occasion to apply a dressing to the child's arm five days before the onset of the first convulsion, the lesion having been traumatized by a fall while at play on his premises. The customary inflammatory phenomena were present as the result of the vaccination and the process of development was normal so far as could be distinguished by the eye. The boy continued with his school duties until November 25, when he was taken with a slight convulsion, after a day or two of malaise. On November 27 his condition was such that it was deemed advisable by his parents to call a physician. Accordingly, Dr. C. C. Emerson of this city visited the child at his home, and, after an examination, pronounced the disease tetanus. The result of his in-

vestigation was communicated at once to the Health Department, where considerable apprehension was occasioned by the appearance of a second case in such swift succession. An attempt to obtain a sample of the virus employed in this case was as unsuccessful as in the previous one. At the invitation of Dr. Emerson I called to see the patient, finding as the result of my examination a condition which was unmistakably tetanus, the symptoms being well marked. With the onset of the disease an active treatment was at once instituted, consisting of large and frequently repeated administrations of antitetanic serum together with sedative and supporting remedies of an appropriate character. The further history of the case is not material in this connection beyond the statement that after a somewhat protracted illness, extending over a period of upwards of six weeks, and despite a very unfavorable prognosis, a complete and satisfactory recovery was effected, the patient returning to his school duties in the latter part of January, 1910.

The technique of the vaccinal operation as practised by the Department at the time of these cases and at the present, and at no time deviated from, is as follows: The arm selected for the purpose having been exposed, the skin surface of the site is carefully cleansed by a preliminary washing with soap and water, a strong preparation of green soap being employed and applied on a pledget of cotton. After this preliminary toilet the skin is rinsed with clean water and then given a copious washing with 95 per cent. alcohol, administered with some friction. After the alcohol has evaporated the vaccination is done, an individual glycerinated glass point being used for each patient. The circular scarification is usually employed by the Department, with at times the linear, the former, however, being believed to result in the most symmetrical and pleasing cicatrices. A dry gauze dressing is at once applied in such a manner as to afford protection from the sleeve or other source of possible contamination.

Especial interest in connection with the two histories recorded above naturally centers around the question of the causation of the tetanic infections, or, more properly, around the determination of the exact dates of the entrance of the tetanus bacillus into these two patients, it being taken for granted that the entrance was effected through the avenues afforded by the vaccinal operations, no other portals presenting themselves in the course of careful investigations made for the purpose of establishing their possible existence. Three possibilities for infection seemed apparent, viz., that the bacillus was present in the virus and entered with it; that it was present upon the person of the patient, physician, or some article employed in the operation and not eliminated by the preliminary sterilization; or that it entered at some date subsequent to the time of vaccination as the secondary or supernumerary infection.

In the consideration of these two cases one is very forcibly impressed with two facts, viz., 1, the remarkable lapse of time between the operations and the appearance of the initial symptoms of tetanus, *i.e.* the apparent incubation period; and 2, the fact that *in neither of the two schools* attended by these children, in which so large a number of vaccinations was performed on the same days, did another case develop, *nor, in fact, in any other school, or in the city*. As regards the length of time elapsing between vaccination and the appearance of tetanic symptoms, this was in Case I twenty days, and in Case II twenty days, the normal incubation period for tetanus, as allowed by common consent among the authoritative writers on this subject being from seven to fourteen days. An inspection of the previously reported instances of this disease as a complication of vaccination, as collected and analyzed by McFarland,[1] shows that an average of twenty-two and one-half days has elapsed between vaccination and first symptoms, while the figures as given by Willson in his collection show an average of seventeen days.

Considering the uniformly prolonged incubation periods in all of these cases, the inference would clearly seem to be, aside from prejudice, that at least the great majority of these cases of tetanus resulted, not from contaminated virus, or from carelessness at the time of the operation, but, as a matter of fact, from secondary inoculation of the wound with the tetanus bacillus at a period of a week or more after the vaccination, unless, indeed, it be claimed that the coincidence of the vaccine matter with the organism of tetanus exerts a decided and uniform inhibitive influence upon the activity of the latter, which hypothesis to the present time has not been demonstrated. The second fact is equally, if not more, impressive than the first, for, considering the large number of pupils vaccinated simultaneously with each of these children in the same and in other schools, under precisely similar circumstances, it is absolutely impossible rationally to accept the hypothesis that the bacilli were present in the virus and were introduced into the patients through it at the time of the operation, since in neither of these schools did another case appear, nor in any other, beyond the two mentioned, either within the normal period or at any later date. In each of the two cases we would have a right to expect others, at least to the extent of nine, since in each box of points from which these children were vaccinated there were nine other points of virus, put up at the same time and in all likelihood from the same strain of vaccine.

Viewed in the light of these facts, therefore, it would appear that we are justified in assuming that the bacilli gained entrance to these patients, not at the time of vaccination, either through the virus, or as the result of careless technique, but at some time subsequently, in the neighborhood of a week after the operation, through a secondary infection. Material weight is added to this opinion when we consider that exceptionally favorable opportunities presented themselves for such secondary infection, at about that period after vaccination, in each case. In Case I, as cited above, the family moved from one house to another at the time when the vesicle was maturating, and that at the same time that carpets were being taken up and dusted, closets ransacked, and the dirt and dust of months were being spread broadcast throughout the house, the arm of this child was being tended and dressed by its mother and others of the family who at such a time, if ever, would hardly be expected to observe very rigorously the precepts of asepsis. In Case II there is a history of the patient's having played in a yard and consequently having been more or less exposed to such germ life as was in the soil, and of his arm having been dressed on one occasion by a relative, who was a teamster, after an

injury to the vaccine lesion five days before the onset of the symptoms of tetanus. As to the possibilities for contamination of the vaccination wound by bacteria, especially by such as make their habitat in earth and about barns, comment is scarcely necessary.

In 1896 this question was taken up by the British Royal Vaccine Commission, with the result that but one case could be found in which tetanus had occurred as a complication of vaccination, and at that time it was absolutely unknown on the continent of Europe. To the present date practically all of the cases recorded have occurred in America. In the study of this subject by McFarland, to which allusion has already been made, occur the records of ninety-five cases, which represent the sum total up to 1902, when his paper appeared. This paper bore excellent fruit, inasmuch as it was largely instrumental in drawing attention to the desirability of all possible precautions in the preparation of vaccine, and to this end were inaugurated improved methods in the laboratories and in the inspection and testing of all virus sold in this country, by officials of the United States Government. The requirements at this time are highly rigorous and leave little opportunity for the dissemination of contaminated vaccines. To-day no lot of virus is put upon the market in this country until it has been repeatedly inoculated into test animals and the result has been observed.

McFarland's conclusion "that the tetanus organism may be present in the virus in small numbers and that an overwhelming proportion (of cases) occur after the use of a particular virus" would seem to indicate that in his opinion at least some of his cases were the result of infection at the time of vaccination. Willson's conclusion is that the tetanus organism enters as a secondary inoculation, some days after vaccination. Welch and Schamberg,[2] in alluding to this matter, state: "We believe from a study of the recorded instances of this complication that the tetanus infection was in the great majority of cases received into the system at a period subsequent to the insertion of the lymph." It is indeed remarkable, considering the frequency of vaccination and the prevalence of the germ of tetanus, that so few cases are to be found in which tetanus has occurred—which speculation might, with equal propriety, be extended to the trivial wounds of other character occurring in everyday experience.

Cases such as the above are at least instructive, as demonstrating the need for increased carefulness in the after treatment of the vaccine lesion, and it would seem advisable that Departments of Health and those in charge of public vaccination should endeavor to bring about some more perfect system of post-vaccinal hygiene.

In the city of St. Louis serious complications following public vaccination have been extremely rare. During the past three years, in a total of upwards of 30,000 vaccinations by the Health Department, these two cases reported above are the only ones that were in any sense serious and embrace the only death that could, in any way, be attributed to the operation.

ASTHMA AND THE LUNG REFLEXES OF ABRAMS.

By ALBERT ABRAMS, A.M., M.D.,

SAN FRANCISCO, CAL.

In several issues of the *Lancet* a polemic[1] was waged anent the lung reflexes, and among the disputants, A. G. Auld of London seems to have most fully interpreted the significance of the reflexes in question. It appears that the controversialists ignored the lung as a factor in the lung reflex phenomenon, and referred the later to some recondite condition of thoracic expansion or to some change in the thoracic musculature.

Indeed, one disputant positively affirmed that the question could only be solved by the vivisectionist investigator, thus ignoring the many valuable data which have been contributed to physiology by the clinician as well as the numerous observations of the latter which have discredited investigations emanating from the physiologic laboratory. Neither the pathologist nor the physiologist should forget that "pathology is the physiology of the sick," and that the final court of decree of the clinician is neither the physiological nor pathological laboratory.

In a recent work by Leonard Hill[2] the following obscure observation is made: "Even now most medical writers ascribe the reflex contraction of the lung (Abrams' reflex) which follows any stimulation of the chest wall to the action of the bronchial musculature. It is more probable that the retraction of the lung is due to a reflex contraction of the musculature of the body wall."

The misconception concerning the lung reflex implicates two factors: (1) A failure to differentiate two distinct lung reflexes; (2) A failure to properly interpret the rationale of the reflexes in question. These reflexes are of the greatest importance in diagnosis and their correct interpretation is destined to solve many obscure problems concerning the pathology of the lungs.

Recently, the writer has investigated the reaction of the lung reflexes to atropine and adrenalin and believes that the pharmacodiagnostic inferences from these investigations may prove of some value.

*The Lung Reflex of Dilatation.**—This is a lung dilatation which is evoked in a variety of ways, notably by cutaneous irritation. Thus, if the skin of the precordial region is vigorously rubbed, the ensuing lung-dilatation may be sufficient to obliterate all evidence of cardiac dullness. If, for example, the skin of the thorax in the right axillary line is irritated there is a dislocation of the lower border of the lung averaging 6 cm.

By the method cited one elicits a circumscribed lung reflex of dilatation, but both lungs may be brought into a condition of temporary acute dilatation (diffused lung reflex of dilatation) by any of the following methods: (1) Percussion of the epigastrium; (2) Irritation of the nasal mucosa; (3) Concussion of the spines of the third to the eighth dorsal vertebræ inclusive.

The Lung Reflex of Contraction.—This is a lung contraction which, like the former reflex, may be elicited in a variety of ways, notably by vigorous percussion over any part of the area of the lung. Fixing a pleximeter over any region, it is struck a series of vigorous blows by means of a plexor.

*The lung reflexes and their employment in diagnosis and treatment are exhaustively discussed in the author's recently published book on "Spondylotherapy."

It will be noted that a circumscribed dullness (lasting but a few seconds) will supplant lung resonance over any region thus concussed.

Observed with the *x*-rays after the blows are struck, the adjacent lung area becomes gradually dark, showing that the air has been expelled from the lungs, whereas in a few seconds the lung area becomes bright again. The lung reflex of contraction cannot be obtained if the nasal mucosa has been previously cocainized.

This reflex may be elicited from definite spinal segments so that both lungs are brought simultaneously into a condition of contraction and, when the reflex is thus evoked, it proves of great therapeutic value in the treatment of asthma.[3]

If, after having first accurately determined by percussion the lower lung borders posteriorly, one concusses the spines of the fourth and fifth cervical vertebræ one notes that, in the norm, the lower lung borders retract from 2 to 5 cm. In pulmonary disease this retraction is either absent, diminished, or accentuated.

Rationale of the Lung Reflexes.—Aufrecht[4] has shown that the musculature of the finer bronchi consists of a stout layer of circular and a weaker layer of longitudinal fibers.

The clinical observations of Abrams,[5] in 1896, which were subsequently confirmed by the physiological investigations of Dixon and Brodie[6] in 1903, demonstrate that the vagus contains fibers which can either dilate or constrict the bronchi.

Both lung reflexes are mediated by vagal action; the lung reflex of dilatation by the bronchodilator, and the lung reflex of contraction by the bronchoconstrictor fibers in the vagus.

The Atropine Test.—As is well known to physiologists, atropine paralyzes the motor endings of the vagus. An injection of 0.001 gm. (gr. 1-60) will manifest its action within thirty minutes after the hypodermatic injection and disappears in from one to three hours. This action has already been utilized in the diagnosis of bradycardia.[7] It will be noted that after the atropine injection, both lung reflexes are *absolutely abolished*.

It is well known that small doses of pilocarpine are almost exactly antagonistic in their action to atropine, and this applies in all cogency to their action on the vagus. After a hypodermic injection of pilocarpine (gr. 1-10), one may note an exaggeration of both lung reflexes. Thus, before the injection of pilocarpine, the lower lung border posteriorly could be made to descend (lung reflex of dilatation) 4 cm. after cutaneous irritation, whereas after the injection the border in question descended 7 cm. The lung reflex of contraction before the injection lasted 20 seconds, whereas after the injection it lasted fully one minute.

Adrenalin Chloride.—After a hypodermatic injection of 8 minims of a 1:1000 adrenalin chloride solution, the following phenomenon was observed: After cutaneous irritation the lower lung border, instead of descending as in the norm (lung reflex of dilatation), receded from 2 to 4 cm. In other words, cutaneous irritation elicited the lung reflex of contraction in lieu of the counter reflex of dilatation.

Practical Deductions.—If one accepts the prevailing opinion that asthma consists essentially of a spasmodic constriction of the bronchioles, then an appropriate dose of atropine which paralyzes the bronchial musculature through its action on the motor endings of the vagus must invariably inhibit an asthmatic paroxysm. Here, the action of atropine, as some assume, is not caused by a dilatation of the bronchi, because the action of the drug is to paralyze the dilator as well as the constrictor fibers of the bronchial musculature.

Atropine in sufficiently large doses is one of the most satisfactory drugs in asthma and, aside from its action in inhibiting bronchospasm, it diminishes secretion, reduces the sensitiveness of the mucous membranes to reflexes, and stimulates the respiratory center.

Now, as a matter of fact, all asthmatic paroxysms do not yield to atropine, hence one is constrained to conclude that bronchospasm is not the invariable concomitant of asthma. There may be a hyperemia of the bronchial mucosa analogous to urticaria, a swelling of the same mucosa, or even exudative bronchiolitis.

Determining the tonus of the lung reflex of contraction is an important test in differential diagnosis. In asthma, due to a defective bronchial musculature, the lung reflex of contraction cannot be elicited.

A supposed spasmodic factor in the pathology of pulmonary diseases must yield to atropine and in this sense atropine is of diagnosticotherapeutic value.

Adrenalin chloride (in doses from 8 to 15 minims hypodermatically of the 1:1000 solution) is one of the most efficient agents in inhibiting an attack of asthma. The action of this drug was discovered by Kaplan and Bullowa, and it may truly be regarded as a specific in arresting paroxysms of asthma.

As noted in the investigations of the writer, adrenalin chloride evokes the lung reflex of contraction which permits the longitudinal fibers of the bronchial musculature to expel the residual air imprisoned by the spasm of the circular fibers.[8]

It is, futhermore, evident that, in our employment of drugs in the treatment of asthma, it is irrational to combine atropine and adrenalin in the same prescription.

246 Powell Street.

A Case of Audible Tinnitus.—H. Tilley reports the case of a girl aged 13, who sought advice for a "purring" noise in her right ear, which she had noticed for at least two years, but which had become louder during the past twelve months after an attack of "influenza." Hearing in both ears was normal, and no pathological conditions were to be seen in the meatus nor in the nasopharynx. The general health was excellent. She has menstruated once—about four months ago—but this seems to have exerted no influence for good or evil upon the aural symptom. Listening through the otoscope, it was noted that: (1) The "purring" sound—very like a hemic murmur—was best heard when the head was erect, and it was synchronous with the pulse. (2) It was diminished by either very light pressure over the right carotid artery, or by much firmer pressure on the left. Tilting the head toward the left shoulder had also a similar effect. The pulsating murmur could be heard in a quiet room if the observer's ear was placed close to the patient's right ear, and was just perceptible if a stethoscope was applied to the temporal bone above the pinna.—*Proceedings of the Royal Society of Medicine.*

THE ORGANIZATION AND WORK OF THE UNITED STATES PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

ONE of the most instructive papers read before the American Public Health Association, the meeting of which was held at Milwaukee, on Sept. 8, 1910, was that by Surgeon-General Walter Wyman describing the organization and work of the U. S. Public Health and Marine Hospital Service. The commissioned officers of the service number 128, and, needless to state, are carefully selected for both their professional and physical qualifications. Commissioned officers are admitted to the corps when under the age of thirty and they hold the position for life. These are stationed at the more important ports where it is necessary to be possessed of experience and training not only in sanitary matters, but in tactful and somewhat diplomatic methods. Acting assistant surgeons are appointed, not by the President, but by the Secretary of the Treasury under civil service rules, and their term of service may be long or short at the pleasure of the Secretary. They are exempted from the civil service rules at foreign ports. These number 274, making a total of 402 in the medical corps. Officers of the corps are stationed at ports in all parts of the world, indeed, at most of the ports in which there is a United States Consulate. As a rule, the regulations for foreign ports are enforced by the consuls, and the duties of the medical officers begin only when medical assistance to the consul seems imperative. No promulgation of quarantine against a foreign port is required. The consul enforces quarantine on his own initiative as soon as he learns of a sudden outbreak of infectious disease. Sometimes, however, they are specially directed from Washington, as recently on account of cholera in Russia and Italy they were ordered to enforce the detention of immigrants en route to America from the infected countries and disinfection of their baggage. Officers are to be found in the principal ports of South America as well as in the several fruit ports of Central America to enforce the regulations regarding fruit vessels. Routine work, however, is not their sole duty; in addition they write important and instructive reports on sanitary conditions and prevailing diseases, which are published by the Bureau at Washington. Their salaries are paid from the fund annually appropriated by Congress known as the epidemic fund, which is for the prevention of the introduction and spread of certain diseases, viz., cholera, yellow fever, smallpox, typhus fever, and plague. This fund can be used against no other diseases than those specified.

It goes without saying that their services are called for in the Philippine Islands, where eleven of them supervise the carrying out of the quarantine. In Hawaii, again, the ten officers of the corps have done and are doing valuable work. The results of their investigations with regard to leprosy have been referred to recently in the MEDICAL RECORD and on several previous occasions. Porto Rico has nine officers, whose duties are to enforce the quarantine regulations relating to Porto Rico and national quarantine. Two commissioned officers are in the Canal Zone at Ancon on the Pacific and at Colon on the Atlantic. These officers are lent to the Isthmian Canal Commission.

Fifty medical officers of the service are engaged in quarantine inspection at the ports of the United States. At three or four ports inspection is made by a State quarantine officer, a survival of the system which prevailed up to 1893. Seventy medical officers are stationed at the principal ports of entry of the United States for the purpose of examining immigrants. In order to convey a clear impression of the magnitude of this task it may be mentioned that during the past year no fewer than 1,280,000 immigrants were thus examined, 30,000 of whom were rejected on account of physical and mental defects. When, too, epidemic diseases break out in the interior of the country officers are requisitioned to suppress such epidemics. A shining example of their activity in this sphere of their duties was that of California when bubonic plague was present in that State. The valuable and even heroic nature of their work on that occasion has been commented on editorially more than once in the MEDICAL RECORD. At the present time some of the members of the corps are endeavoring to exterminate bubonic plague among the ground squirrels of California. In other places the Public Health Service is investigating other diseases than those named in the epidemic law, viz., typhoid fever, infantile paralysis, cerebrospinal meningitis, hookworm disease, pellagra, dengue fever, milk sickness, etc. It should be stated that in this work the service cooperates with the State Health authorities. Referring to the State boards of health, General Wyman says that they are growing in power and efficiency, although the boards of some States are deficient as to laws, equipment, or appropriations.

Research work during the past year at the Hygienic Laboratory included tuberculosis, with special reference to the blood and transmission of the disease by milk; typhoid fever and hookworm disease, the longevity of their causative agents and means necessary for their destruction in nature; typhus fever and its transmission by the body louse; pellagra; infantile paralysis; cancer in the lower animals; the "straw mattress disease"; immunity; the oxydases, with reference to their defensive action in the animal body; the influence of bleaching on the nutritive value of flour; therapeutic prop-

erties of the thyroid and suprarenal glands and their commercial preparations. Much valuable work was also done in connection with rabies.

There are numerous marine hospital relief stations on the sea coast, lakes, and rivers throughout the United States, twenty-two of them being hospitals owned and operated by the Government. These furnish the means for training the medical corps in governmental work; 51,500 patients from the merchant marine were treated therein during the past fiscal year. At the Sanatorium for Consumptive Seamen at Fort Stanton, N. Mex., which is under the charge of the service, 350 patients are treated annually.

The Bureau of the Public Health and Marine Hospital Service at Washington consists of seven divisions, each presided over by a commissioned medical officer. These are: (1) Scientific research and sanitation. (2) Foreign and insular quarantine and immigration. (3) Domestic (interstate) quarantine. (4) Sanitary reports and statistics. (5) Marine hospitals and relief. (6) Personnel and accounts. (7) Miscellaneous division. Through the division controlling maritime quarantine 16,766 vessels were inspected during the last fiscal year at domestic, insular, and foreign stations, involving inspection also of 1,433,134 persons and the disinfection of 1,603 vessels. This division supervises the medical inspection of immigrants. Under the division of domestic quarantine the operations with regard to plague on the Pacific Coast are conducted, besides other State work. The Division of Sanitary Reports and Statistics compiles and publishes each week Public Health Reports. It is announced that a compilation is in preparation of State laws bearing upon the reporting of diseases with a view to increasing the collection of morbidity statistics and bringing about improved methods and greater uniformity in their collection.

The address of General Wyman was a remarkably lucid exposition of the manifold duties and research work performed by the able and energetic body of men over which he holds the command. The account of the organization and work of the service should be made known throughout the entire country for the benefit both of those who oppose the creation of a Department of Public Health in Washington and of those who favor it, many of whom are in ignorance of the multiplicity of duties which fall to the lot of the officers of the service and of the highly valuable research work done at some of the stations and at the hygienic laboratory. Here is really a Department of Public Health already in working order, although hampered by red tape and by the fact that it is only a bureau in the Treasury Department. Only a little legislation, and that not radical, would be needed to make an independent department out of this well-organized and efficient body of practical sanitarians.

The Cholera in Italy.—The official bulletin issued in Rome on November 1, reported six new cases of cholera in the preceding twenty-four hours, two in the Province of Caserta, three in the Province of Salerno, and one in the Province of Palermo. Two deaths occurred in the same period.

DEVELOPMENT OF MEDICAL INSTRUCTION AT BERLIN UNIVERSITY.

That a great medical university is no place for teachers who are mere figureheads, stopgaps, absentees, etc., is shown in the issue of the *Berliner klinische Wochenschrift* of October 10, which is devoted entirely to a retrospect of the teaching body of the past, through a series of essays by the present incumbents of the various chairs. This principle of efficiency is as old as education itself, but has never obtained anything like universal acceptance, because the smaller institution is always in the majority. When several smaller schools consolidate and one special chair has to be filled instead of a number, the chances for filling this chair with an efficient man are naturally proportionally greater. In anatomy, for example, it should be possible to fill the chair with an enthusiast, at least, to the exclusion of the indifferent man who accepts the position under protest, and who has to teach himself daily to make any showing at all with his class. If the consolidated school is endowed, it is naturally not difficult to lay hold of a teacher already famous. But the small school is by no means always at fault, for it has happened that some of these have had "all-star" faculties—this naturally in the days when but few chairs were required; and it has happened and perhaps still happens that great and even endowed schools have as the incumbents of the chairs inefficient men, who have done absolutely nothing to demonstrate fitness for their work. Such men are or ought to be mere honorary professors, for the real teaching body, which confers renown on the school, is found in some of the associate, adjunct, and clinical professors.

In prescientific days, or, in other words, well into the nineteenth century, the incumbents of the Berlin chairs did little to distinguish themselves, although many of them wrote text-books. But coincident with numerous epoch-making discoveries in chemistry, biology, minute anatomy, physiology, and pathology, when the opportunity for efficiency at last presented itself, appears the name of Johannes Müller, whose fame is constantly increasing as one who taught many of the great teachers who succeeded him. Müller taught anatomy, physiology, and pathology at the same time; and since his day all chairs evolved from this parent institution have been worthily filled. Among incumbents are Reichert and Waldeyer in anatomy, and Hertwig in embryology, whose monumental works are well known. The chair of physiology had such incumbents as du Bois-Reymond, who taught many of the men who afterwards became famous throughout Europe, and Rubner, the present holder. Müller's successor in pathology was Virchow, who held the chair with such renown for so many years, and whose death occurred not so long ago. The work done in the institute of pharmacology by Liebreich from 1883, the date of its establishment, to 1908 must be mentioned. Of the chair of internal medicine, beginning with Schölein, one of the founders of scientific medicine, the incumbents were Frerichs and von Leyden for the first medical clinic, Traube and Gerhardt for the second medical clinic, and

Hufeland, Romberg, and Senator for the poliklinik. The clinic for children's diseases is represented by the names of Henoch and Heubner, and that for psychiatry by Westphal, Jolly, and Ziehen.

In surgery the first incumbent of the university at the time of its reorganization a century ago was von Graefe, who was also a pioneer in ophthalmology. He was followed by Dieffenbach, von Langenbeck, von Bergmann, and Bier. In the surgical clinic at Charité Hospital we find such names as von Bardeleben and Koenig, with Gusserow and Bumm in the gynecological clinic. The latter is not to be confounded with the university clinic for gynecology and obstetrics, held by the following succession of teachers from its outset—Siebold, Busch (who taught some of the greatest modern specialists), Martin, Schroeder, and Olshausen.

Space hardly suffices to complete this series. It is enough to state that all other chairs have had equally strong representation. All the names mentioned and which might be mentioned are or should be familiar to the profession as a whole; but when we look from the mere names themselves to the incredible amount of work done by the bearers—the illustrious pupils instructed, the volume of literature, the museum specimens, the innumerable advances made in the science and art of medicine—imagination must fail us. No one reaches a chair without first having shown himself worthy, and no one can hold his position without continually showing his fitness for it. While some of our great universities have long ago adopted this necessary course of procedure in filling chairs, a study of these papers in the *Wochenschrift* should possess much value for our medical schools in general. No chair ever made a teacher great, yet the thoughtless sometimes look upon any honorable position as they do an honorable title as the making of the man. Look at the significance of the magic phrase among the laity "he is professor in the college."

It is true that the very greatest university cannot always possess an "all-star aggregation of teachers." Hardworking teachers have a tendency to overwork, or may fall victims of disabling diseases. There may be interregnums,in which the department is not filled at all, or filled by an emergency man. A few men may profit unfairly by the special ability of their assistants. There may be men fully equipped for the best teaching who never receive recognition. In the United States it is largely because of this class of men that new schools have continually arisen. The proper incumbent of a chair is evidently the hard and constant toiler, rather than the merely brilliant man. Whatever else he is he must be a glutton for work. Next in order would appear to be the ability to inspire others to toil as he does, and to give them tasks which lead to something. Brilliancy, as shown in snap diagnoses and dexterous operating, plays a relatively small part in university teaching.

SYMPOSIUM ON 606.

At the eighty-second meeting of the Deutscher Naturforscher und Aerzte at Königsberg on September 20 last over thirty contributions on this subject were made in some form. A considerable number of papers were read outright, while numerous reports were submitted by those to whom the remedy had been sent. Abstracts of these papers occupy the entire originalia of the *Deutsche medizinische Wochenschrift* for October 13. This immense body of data is nowhere summed up in any manner to determine the consensus of findings. Many have already expressed their views in previous papers, notably Ehrlich, Alt, Wechselmann, and other pioneers. We may assume that their views can have undergone but little change.

Neisser, Iversen and others confirm their original views with frank enthusiasm. Salmon of the Pasteur Institute, Paris, in speaking of prophylaxis, states that if a married man developed a suspicious sore he would at once infect the wife. He regards tuberculosis as a contraindication. As to dosage there is no relationship between it and the degree of disease. The most severe and malignant type requires only a medium dose. Schindler states that himself and Canstern appear to be the only reporters who have encountered primary sores which resisted 606. Ledermann has seen no unpleasant effects save tachycardia. Others have noted insomnia, troubled sleep, anorexia, constipation, orchodynia, retention of urine, slight rise of temperature, etc. There is naturally much activity in connection with results of treatment in parasyphilis. As far as a cursory perusal can inform the reader such results were negative or doubtful. The incidental disappearance of conditions usually amenable to arsenic is sometimes noted (psoriasis, lichen).

Many writers dwell on details of technique and methods of preparing injections. Others touch on the relationship between the treatment and the Wassermann reaction, and on the association of 606 with other remedies. Quasi-miraculous cures of syphilis maligna seem, if anything, to be increasing in greater ratio than others. It seems paradoxical that when the most inveterate and severe forms yield so marvelously, that the milder and earlier forms should not yield at least as readily. It has been claimed, however, that spirochetes are much less numerous in severe tertiary forms, the severity of the disease being due to acquired supersensitiveness. Hence the fewer spirochetes present the more rapid the cure. With the death of these in severe tertiary syphilis, the supersensitiveness is no longer in evidence and the patient has enough latent vitality to recover.

Although the papers are nominally devoted to syphilis, several reporters mention the treatment of other spirilloses and trypanosoma diseases, especially in animals, in which repeated doses caused neither aniphylaxis nor unpleasant consequences. It is confidently believed that 606 will prove as efficacious for many of these maladies as for syphilis.

Restraining the Nostrum Vendor.

The Illinois State Board of Health has won an important victory in its war on quackery in that State. The medical practice law of the State places the itinerant medicine vendors under the control of the State Board, they being compelled to obtain a license from the Board, paying therefor a fee of

$100 per month. In the present instance the Board had a vendor arrested for not having procured a license, but he pleaded that he had not violated the provision of the medical practice act in that he had not professed to cure with the remedies he sold. The lower court decided in the defendant's favor, but the Supreme Court has now decided that the State Board was within its powers in demanding that this man, and by inference all other patent medicine vendors, should first procure a license and pay the fee, even though he had not upheld by word of mouth the claims to cure made on the labels and wrappers of the nostrum which he sold. Illinois is, we believe, the only State exercising control over itinerant vendors of patent medicines who do not combine the vending with advice which would render them liable to the charge of practicing medicine. Of course this does not affect the sale of nostrums by druggists, but they are not the only, if indeed the chief, agents in the wholesale poisoning or defrauding of the people. The most profitable market for patent medicines is not in the cities, but in the small settlements and farming districts, where the nostrum peddlers go from house to house vending their remedies, often stocking farmhouses with a supply left on trial. They know full well no one can resist a bottle of cure all, with the virtues of the remedy and the symptoms for which it is good all attractively emblazoned forth on the label. So when they call again they find a bottle used, collect the price, and have more of the same kind or something else. The regulation of suppression of such a trade is an important duty of a health board, and it would be well were the medical practice or the health laws of every State so amended that a practically prohibitive tax could be put upon this nefarious trade.

News of the Week.

Army Medical Corps Examinations.—The Surgeon-General of the Army announces that the first of the preliminary examinations for the appointment of first lieutenants in the Army Medical Corps for the year 1911 will be held in January 16, 1911, at points to be hereafter designated. Full information concerning the examination can be procured upon application to the "Surgeon-General, U. S. Army, Washington, D. C." The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice after graduation. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received in order to lessen the traveling expenses of applicants as much as possible. The examination in subjects of general education (mathematics, geography, history, general literature, and Latin) may be omitted in the case of applicants holding diplomas from reputable literary or scientific colleges, normal schools, or high schools, or graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School. In order to perfect all necessary arrangements for the examination, applications must be complete and in possession of the Adjutant-General on or before January 3, 1911. Early attention is therefore enjoined upon all intending applicants. There are at present seventy-six vacancies in the Medical Corps of the Army.

Civil Service Examination.—The United States Civil Service Examination announces an examination to be held on November 23, 1910, for the purpose of securing eligibles from which to make certification to fill vacancies as they may occur in the position of physician in the different services. As an insufficient number of eligibles to meet the needs of the Indian and Isthmian Canal services resulted from the examination held on September 14, qualified persons are urged to enter this examination, to which men only will be admitted. Application for the manual containing the necessary information and for the proper blanks should be made to the United States Civil Service Commission, Washington, D. C.

Deaths in Childbirth.—Dr. F. S. Crum writes that one of the ratios in his recent article entitled "Deaths in Childbirth" was incorrect, the decimal point being wrongly placed. The fatality ratio of the Society of the Lying-in Hospital of New York City should have been expressed as 44.3 per 1,000 of total confinements, instead of 4.4. This correction would, of course, change also the reading of the third paragraph. The Society of the New York Lying-in Hospital experience showed about 2.6 times higher fatality ratio than the experience of the Boston Lying-in Hospital.

City Death Rate.—For the week ending October 22, the death rate in New York was 13.78 per thousand of population, representing 1,269 deaths, or 77 less than for the same week of last year, when the rate was 15.38.

Healthy Communities.—East Orange, N. J., can now lay claim to the lowest death rate of any municipality in the country. The Bureau of the Census reports that for 1909 its death rate was 9.5 per thousand of population. The next lowest on the list is Akron, Ohio, with a death rate of 9.7.

Statistical Advisory Board.—Dr. Ernst Lederle, Commissioner of Health of New York, announces that he has secured the assistance of three physicians and two college professors who will act as an advisory board of statisticians to the Health Department. With Commissioner Lederle the Board will comprise Dr. Roger S. Tracy, formerly registrar of the department, Dr. William S. Guilfoy, the present registrar, Dr. Cressy L. Wilbur, Prof. C.-E. A. Winslow, formerly of the Massachusetts Institute of Technology, but now a member of the Faculty of the City College, and Prof. Walter L. Wilcox of Cornell University, who is also consulting statistician of the State Department of Health. The Board will endeavor to outline a plan for the better computation of health and mortality statistics.

Plague in Venezuela.—Because of several new cases of bubonic plague in Caracas the Government of Venezuela has instituted more active measures to fight the disease. Schools have been closed, and services and funerals in the churches have been prohibited. The Bolivar celebration which was scheduled to begin on October 28 has been indefinitely postponed.

Typhoid Fever in New York.—Interesting statistics on the prevalence of typhoid fever in New York State are contained in a report made

recently to Governor White by Dr. Porter, State Commissioner of Health. Comparison is made of the average number of deaths from typhoid during each month for the years 1900 to 1909, with those of the first nine months of the present year, as follows:

Month.	Average 1900 to 1909 Inclusive.	1910.
January	126.1	87.0
February	107.1	87.0
March	108.2	92.0
April	94.4	68.0
May	92.0	63.9
June	74.4	70.0
July	106.2	94.0
August	153.9	131.0
September	192.6	183.0
October	212.2	....
November	170.5	....
December	156.1	....

The figures show that the normal variation of typhoid fever during the year is very marked, and also that the mortality from typhoid fever in the State during 1910 is well below the average. An appreciable excess in the number of cases has occurred recently, however, in Syracuse, Niagara Falls, and Yonkers, the conditions in the last named having been investigated by the health department.

The Harvey Society.—The second lecture of the Harvey Society for the present season which was to have been delivered on Saturday, November 5, at the New York Academy of Medicine, has been postponed owing to the impossibility of Prof. Castle being present on that evening.

College of Physicians and Surgeons.—The total registration for the year at the College of Physicians and Surgeons, New York, is 334, the classes being made up as follows: First year, 81; second year, 88; third year, 90; fourth year, 72; special students, 3.

Dr. Benjamin A. Thomas has been elected Professor of Genitourinary Diseases in the Philadelphia Polyclinic.

Medical Reciprocity.—The State Medical Examining Boards of Kansas and Missouri have adopted reciprocal relations, so that licences to practise granted in one State will be honored in the other. The States have not recognized each other's certificates for a number of years.

American Society of Sanitary and Moral Prophylaxis.—The regular meeting of this society will be held at the New York Academy of Medicine on Thursday evening, November 10, at 8.30 P.M. The subject for discussion will be "The Sanitary Supervision of Prostitutes and Clause 79 of the Page Bill." The discussion will be introduced by Hon. Julius M. Mayer, counsel for the Page bill.

The Alumni Association of the Lying-in Hospital will hold their next meeting at the Harvard Club on Wednesday, November 9. Dr. J. Whitridge Williams (Baltimore) will read the paper of the evening, entitled "My Experience in Labor Complicated by Contracted Pelvis."

The Menard County (Illinois) Medical Society at its annual meeting at Petersburg, on October 20, elected the following officers for the ensuing year: *President*, Dr. T. T. Hill of Athens; *Vice-President*, Dr. Orr of Tallula; *Secretary and Treasurer*, Dr. A. L. Brittin of Athens.

The Colorado State Medical Society at its annual meeting in Colorado Springs, on October 11 to 13, elected the following officers: *President*, Dr. William Howard Swan of Colorado Springs; *Vice-Presidents*, Dr. T. E. Carmody of Denver, Dr. M. J. Keeney of Yampa, and Dr. Samuel French of Meeker; *Secretary*, Dr. Melville Black of Denver. Steamboat Springs was selected as the place for holding the annual convention of 1911.

Fish Diet and Cancer.—Several dogs, so it is stated in a dispatch from Washington, have been sent to the Maine hatcheries of the Bureau of Fisheries, to be fed upon fish (presumably fish with malignant growths) in order to determine whether cancer is communicable in that way. There are many men who would gladly subject themselves to such an experiment at the price of being sheltered and well fed on fresh fish during the winter.

Cholera in an Insane Asylum.—It is reported that the majority of the inmates of an asylum for the insane near Naples have died of cholera during the present epidemic, the deaths numbering from four to seven a day for a fortnight.

The Hookworm in Samoa.—In the annual report of Capt. Parker, U. S. N., governor of the American Samoan Islands, it is stated that uncinariasis is extremely prevalent in the islands, no less than 85 per cent of the natives being affected. The disease was discovered accidentally by a naval medical officer and an investigation was then instituted which led to the finding of 5,700 cases among the native population of 6,780.

The Straus Milk Stations in this city will not be discontinued, it is stated, Mr. Nathan Straus having been persuaded to reconsider his announced intention of giving them up. The determination to discontinue them was formed in consequence of bitter personal attacks by a newspaper of this city, but a committee of physicians and philanthropists convinced Mr. Straus that the newspaper did not express the sentiment of the community.

Pneumonic Plague in England.—A number of cases of pneumonic plague have been discovered in Preston, a village in Suffolk, England, and at the same time many rats and rabbits have been found dead in the fields. The introduction of the disease is attributed to plague infested rats in grain transports from Odessa.

Death of the Founder of the Red Cross.—M. Henri Dunant of Geneva, founder of the Red Cross Society, died on October 30 at Hilden, Switzerland, aged 82 years. His attention was turned toward the needless suffering in war when he took part in the battle of Solferino in 1859, and he then initiated an agitation which led to the calling of an international conference by the Swiss Government in 1863, followed in 1864 by the Geneva Convention. At this convention nine articles were adopted, signed by twelve and later by forty governments, "for the amelioration of the condition of the wounded in armies in the field." The Society of the Red Cross was established at this time, through the labors of M. Dunant, to carry out the provisions adopted by the Convention.

Obituary Notes.—Dr. Frederick Holme Wiggin of New York, a graduate of the Bellevue Hospital Medical College in 1877, consulting surgeon to the City Hospital, visiting gynecologist to St. Elizabeth's Hospital, and consulting surgeon to the Metropolitan Throat Hospital and the Litchfield County Hospital of Winchester, Conn.; a member of the American Medical Association, of which he was at one time vice-president; a former president and secretary of the New York State Medical

Society, and a former president and vice-president of the Society of the Alumni of Bellevue Hospital; a member of the New York Academy of Medicine, the Harvey Society, the Medico-Surgical Society, the Connecticut State and Litchfield County Medical Societies, the Vermont State Medical Association, and the New York County Medical Society, and an honorary member of the Congress of German Surgeons, died at Atlantic City, on October 28, after a long illness, aged 57 years.

Dr. John E. Allen of New York, a graduate of the Bellevue Hospital Medical College in 1875, for twenty-five years a member of the Department of Health of the City of New York, died at his home on October 25.

Dr. Harry B. Lochhead of Pittstown, Pa., a graduate of the Jefferson Medical College of Philadelphia in 1902, and a member of the Pennsylvania State and Luzerne County Medical Societies, died at the White Plains Hospital, on October 25, aged 35 years.

Dr. Shelton Law of Springfield, Ill., a graduate of the Baltimore University School of Medicine in 1897, died at his home, on October 22, aged 38 years.

Dr. Edgar R. Knapp of Saginaw, Mich., a graduate of the Department of Medicine and Surgery of the University of Michigan, Ann Arbor, a veteran of the Civil War, died at his home, on October 19, aged 76 years.

Dr. James McC. Duncan of Pawnee, Ill., a graduate of the Miami Medical College, Cincinnati, Ohio, in 1892, a member of the American Medical Association and of the Illinois State and Sangamon County Medical Societies, died at his home on October 16.

Dr. Louis Auerbach of Denver, Col., a graduate of the University Medical College of Kansas City, Mo., a member of the American Medical Association and of the Colorado State and Denver County Medical Societies, died in St. Luke's Hospital, Denver, on October 14, aged 58 years.

Dr. Martin L. Corbin of Ellenboro, W. Va., a graduate of the Kentucky School of Medicine in 1892, and a member of the American Medical Association and of the West Virginia State and Ritchie County Medical Societies, died at his home, on October 17, aged 58 years.

Dr. George A. E. Carey of Indianapolis, Ind., a graduate of the Cincinnati College of Medicine and Surgery, Ohio, in 1864, a veteran of the Civil War, died at his home on October 14, aged 77 years.

Dr. John W. Hammond of Wellsville, Ohio, a graduate of the Jefferson Medical College of Philadelphia in 1856, a member of the Ohio State and Columbian County Medical Societies, died at his home, on October 18, aged 79 years.

Dr. Charles C. Davidson of Philadelphia, Pa., a graduate of the Jefferson Medical College of Philadelphia in 1880, a member of the Pennsylvania State and Philadelphia County Medical Societies, died at his home, on October 19, aged 62 years.

Dr. Edgar H. Douglas of Little Falls, N. Y., a graduate of Dartmouth Medical College in 1890; a member of the American Medical Association and of the New York State and Herkimer County Medical Societies, and attending surgeon to the Little Falls Hospital, died in the Faxton Hospital, Utica, on October 29, as he was about to undergo an operation for gallstones. Dr. Douglas was 43 years of age.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE SCHORSTEIN LECTURE.—THE HUXLEY LECTURE.—MEDICAL SOCIETY OF LONDON.—SIR W. RAMSEY ON NEW ELEMENTS.—OBITUARY.

London, October 14, 1910.

The Schorstein Lecture at the London Hospital was delivered this year by Dr. Robert Hutchinson, one of the physicans. This lectureship was founded in memory of the late Dr. Gustav Schorstein, who was elected assistant physician to the hospital in 1894, became full physician in 1905, and died in 1906. His earnest work during this time as a clinical practitioner and teacher and his special devotion to children's diseases induced Dr. Hutchinson to take for the subject of his memorial lecture "Congenital Pyloric Obstruction," though fain to admit that to call it "congenital" was to beg one of the most disputed points in the natural history of the disease. Still that was the name first conferred on it and the proposed alternatives are open to the same objection. The lecture then was a clinical one and presented in an interesting manner the experience of a physician who has had the opportunity of studying the several problems that surround it. The history is particularly interesting for though its recognition only dates from 1888 it must have been in existence from time immemorial. This the lecturer regarded not only as an instance of the difficulties of clinical observation but as a humiliating example of a whole profession overlooking for long periods of time what was all the while "lying, so to say, under its nose." The confession may be painful to the clinician, but then the pathologist cannot scoff, for he has just as completely overlooked it on the post-mortem table. The greater frequency of the disease in boys and in the first-born seems to be a fact, but no explanation has been proposed and Dr. Rob. Hutchinson had none to suggest, so he passed on to the symptoms: (1) The peculiar vomiting, projectile in character, and persistent, though there is a tendency on any change of food for it to cease for a few hours and recur as violently as ever. This vomiting comes on a few weeks after birth and is accompanied by pseudoconstipation, from failure of the food to find its way into the bowel. (2) Visible stomach peristaltic waves. They begin at the left side as a rounded swelling below the costal margin and pass across the abdomen obliquely downward to the right and before one wave disappears another comes on so as to form a sort of hour-glass shape across the abdomen. Sometimes three waves may be seen at once. This vigorous peristalsis is just as diagnostic of pyloric obstruction in the infant as in the adult. It is not painful and the infant often lies apparently unaffected by it. (3) A pyloric tumor can sometimes be felt and that would settle the diagnosis. Dr. Hutchinson said this should be felt for to the right of the middle line and they should try to get under the stomach and press the pylorus against the right side of the spinal column. Passing to the pathology the lecturer said that post-mortem there was an enormous increase of the pyloric canal, forming a dense, almost cartilaginous, tube, projecting into the duodenum and the wall of the vestibule was thickened and to some degree the whole stomach and even the lower end of the esophagus displayed thickening. As to how the

condition is brought about two views were held; one was that it was congenital, the other that it arose in consequence of long-continued spastic contraction. The lecturer pointed out the difficulties of both these hypotheses but had no alternative to offer, so recommended waiting for further information, especially as to the condition of the pylorus in those who have recovered and died years afterwards of other diseases. As to the treatment the lecturer confessed that at first he was deeply imbued with the idea that surgery alone could cope with the disease. In fact in his first case in private practice he strongly recommended operation but the parents declined and the child recovered under another doctor. This case converted him to a belief in the efficacy of medical treatment and since then he has seen twenty cases in private practice of which seventeen recovered under medical measures; the other three went to hospital and two of them died. Some others have also recorded nearly as fortunate statistics and so he thought all cases should undergo treatment by careful feeding and lavage for a time—say from three to six weeks before appealing to surgery.

The triennial Huxley lecture was delivered on Monday by Dr. F. W. Mott, Fullerian Professor of Physiology to the Royal Institution and Physician to Charing Cross Hospital. He devoted it to the hereditary aspects of nervous and mental diseases. I need not say he grasped his subject with a master hand. He showed a series of pedigrees and referred to statistics he had gathered from the County Council Asylums, to which he is the pathologist. Cases of insanity, he said, were seldom simple, but were in various degrees inborn tendencies combined with mental or bodily stress or strain on important organs and functions. In the majority of cases transmission was by the female side. The fact that a cousin was insane or even several members of a large stock did not show bad heredity. Often persons of genius come from such a stock. The general tendency was that insanity did not go beyond three generations—there was either a regression to the normal or the stock died out. This often happened by the tendency showing itself in imbecility of adolescence, and such patients were further prone to tuberculosis, and so rotten twigs were continually being broken off the tree of life. The vexed question of transmission of acquired characters, of special interest in relation to alcoholism, was wrapped up in the causes which led a man to drink, and his observations seemed to show that a man who could drink continually for years and keep out of an asylum or a prison had an inherent stable physical and mental organization and he might in a measure transmit this, though his offspring in all probability would have been stronger had he been temperate. Drunkenness in succeeding generations would, however, without doubt lower the virility, mental and physical degeneracy being the result.

The study of pedigrees had confirmed the doctrine of Maudsley that a person did not inherit insanity, but a tendency to it, and further that the tendency was inherited from the stock. The unsound strain in the stock might not be seen as insanity but in some allied neurosis. Conversely these might forebode insanity in the next generation. With the spread of the knowledge of heredity and the cult of eugenics there might be improvement of the human race by the double process of multiplication of the fit and elimination of the unfit. But the study of heredity taught also that the measure of fitness depended largely on inborn characters; "you do not gather grapes of thorns or figs of thistles."

Sir Wm. Ramsay in opening his course gave the class a lively sketch of the search for new elements that had been carried on all over the world and "outside as far as they could go." It had been proved that there were "missing elements." Some 240 minerals had been examined and some gases separated but no element. Water from springs and gases from them yielded nothing new. Then meteoric stones were examined and nothing found which was not known before. At last krypton was discovered in liquid air, and by the same process helium, neon, argon, and xenon. An entirely new light was thrown on the subject by the discoveries in connection with radium. They showed that some elements were not stable, never lasted long enough to allow examination. No one had created or annihilated matter, but in certain forms it changed so rapidly as to be unrecognizable. This was the case with radium emanations. So very small is the amount of radium available, its estimated cost at present being £420,000 for an ounce, that experiments to determine the nature of the emanations had to be conducted on a microscopic scale. It had now been discovered that the gases given off were not merely "mysterious influences or emanations," but that they contained a new element of which the existence would never have been suspected but for the discovery of radium. Still there were some blanks to be filled up.

The first meeting of the 138th annual session of the Medical Society of London was held on Monday. Dr. Samuel West, the retiring president, occupied the chair during the formal business and then made way for the incoming president, Mr. Charters Symonds, who gave his inaugural address, taking for subject "the treatment of chronic abscess of bone by means of metal drains."

Mr. Cecil Huntingdon Leaf, surgeon to the Cancer Hospital, died on the 5th inst. He was a student of the London Hospital, where in due course he became house surgeon, house physician, clinical assistant, and demonstrator of anatomy. He graduated at Cambridge, M.A., M.B., and B.C., and afterwards became a member of the senate of the university. He proceeded to the F. R. C. S. Eng. in 1895. In 1900 he was elected assistant surgeon to the Cancer Hospital and as vacancies occurred passed on to the senior position. A man of great literary power, he wrote for the journals, was one of the reporters of the "*Lancet* Experiments with Chloroform," 1893, and translated French and German works. His "Surgical Anatomy of the Lymphatic Glands" is well known.

Dr. John Anderson, C.I.E., died in North Kensington on the 10th inst., aged 70. He qualified in 1861 and entered the Indian Medical Service, attained the rank of Hon. Brigade-Surgeon and was on the viceroy's medical staff during Lord Ripon's viceroyalty, becoming at that time C.I.E. Returning to England in 1885 he took the St. Andrew's M.D., joined the College of Physicians and began practice in London. He was appointed Physician to the Dreadnought Hospital and to King Edward VII Hospital for Officers. He lectured at St. Mary's Hospital on tropical diseases, on which he was a recognized authority, and on which he contributed to the societies and journals, one of his most interesting papers being on the "Remote Ef-

fects of Tropical Life on Europeans." *Trans. Med. Soc. Lond.*, 1902.

Brigade-Surgeon Lieut.Colonel Rob. N. Macpherson, late of the Royal Artillery and Army Medical Staff, died on the 28th inst., aged 72. He qualified in 1864-5 at the London and Edinburgh Colleges. In 1879 he contributed to the *Lancet* a case: "Stricture Followed by Rupture of the Urethra." He saw fifteen years' service in India and three in the Mediteranean. His last appointment was at the head of the Portsmouth Military Hospital. He has three sons now serving in India.

The death is announced of Dr. Joseph H. Hill, who was Government Medical Inspector of Emigration for the Port of London and had held official positions under the New South Wales government as well as in this country for the United States. He qualified at the Edinburgh College of Physicians, the Glasgow Faculty, and the L. S. A., London, 1867-8. He proceeded to F. R. C. S. Edin., 1872, and took M.D. Brux., with honors, 1879.

Dr. F. W. Dyce Fraser, who died suddenly at the age of 55, was formerly Professor of Anatomy and Physiology at the University of Osaka. Since then he has been on the staff of the Victoria, Children's, and Charing Cross Hospitals. He was an Edinburgh graduate in arts and medicine and F. R. C. P. of the Edinburgh College.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

MIGRATION OF CALCULI FROM THE RENAL PELVIS AND URETER BY TEARING OF THE WALLS—CHOLERA—TREATMENT OF SYPHILIS—NECROLOGY, PROFESSOR FARABŒUF.

PARIS, September 30, 1910.

At the Academy of Medicine, Le Dentu presented an interesting investigation by Tuffier demonstrating by authentic facts that the migration of calculi from the ureter through its walls is possible. In the course of the migration of calculi from the ureter after injury of the walls, the marked infiltration of the urine is not an accident much to be feared or dreaded. The tearing of the ureteral wall is preceded by an active ureteritis and periureteritis. At the point where the calculus is arrested "it makes its nest"; eccentrically compressed, the walls of the ureter end by contracting; the calculus incrusts itself and when the walls are destroyed by the pressure and the inflammation they become torn and perforated. The ureteral walls cicatrize almost immediately after the exit of the calculus; from the moment of the extraction not a drop of urine escapes from the wound. The reason why the infiltration of the urine is sometimes so slight when calculi have been evacuated, and sometimes considerable, may be found in the condition of the tissues around the ureter. If the sclerosis has taken on considerable thickness the tissues oppose an almost insurmountable obstacle to the infiltration of the urine; if they have maintained a certain amount of suppleness they resist badly and a large urinary pocket is formed in the neighborhood of the tear, which remains freely communicating with the canal. In such circumstances the cicatrization of the tear will be inevitably retarded.

Chantemesse has studied the march of cholera through Europe from 1904 to 1910. In September, 1904, the actual epidemic of cholera penetrated Russia by way of Bakou, returning to Persia. In 1906, the cholera reached St. Petersburg; it killed more than 6,000 persons in 1907. In 1908 the cholera reigned in Russia, where its victims numbered 30,000. The extension of cholera continued into Germany and Holland, following special lines. One was the propagation of cholera from place to place; the other was transportation of the disease by a ship or a train. The fight which the Hollanders have undertaken against the invading march of cholera has been victorious. In that country cases of cholera must be reported by any person who observes its occurrence, and that under pain of apprehension and punishment. Immediately the suspected person is isolated as well as the whole family, and that isolation continues until the end of the bacteriological examination, and ceases when this examination is negative. If it is positive, the whole house is emptied and all the persons who have been in contact with the sick person are placed in an isolation pavilion for observation during a time equal to the period of incubation. The individuals kept isolated are supported at the expense of the State, and receive their ordinary salary as if they had worked as usual. This method of defense is certainly expensive, but it has given excellent results in Holland. It shows how an effective defensive method might be instituted against cholera, whose foci are renewed with activity at this moment in Russia.

Emery has published an interesting article in *La Clinique* on the modern treatment of syphilis. It has been acknowledged for some three years that the salts of arsenic have a considerable power as a specific against syphilis, so that we may qualify arsenic as a specific medication for syphilis. Atoxyl has been tried, but this salt has no preventive properties, for it does not prevent recurrences of the disease. If it has an undeniable action against the skin ulcerations, it is much less efficacious against the mucous lesions; atoxyl also is not inoffensive. Hectine was employed with good results, but not of certain nature. Hectine may be considered as an adjuvant of mercury, but should not be substituted for it. Lastly, the discovery by Ehrlich has given truly extraordinary results. That which his product has shown as most remarkable is the rapidity of action of a single dose. If we cannot say as yet that it sterilizes syphilis, we may, at any rate, hope for this result.

The medical world of France mourns the death of the eminent Prof. Farabœuf. His name stands for the perfection of anatomical studies. Convinced that we should not learn anatomy from books alone but also on the cadaver, he created little by little, from diverse elements, the organization of the practical school of the Faculty of Medicine of Paris. Under his direction this soon became the first professional school in the world and served as a model for all others. Farabœuf was not only the creator of the school of practice of Paris, but also a professor extraordinary. His lessons were marvelously vivid and as he knew admirably anatomy, and how to portray it, his demonstrations, always luminous, drew to his course an innumerable multitude of auditors. Farabœuf also created the teaching of operative medicine; he wrote on this subject a marvelous work whose perfection will never be surpassed, and which remains a model that cannot be equaled. Interne of the Hospitals in 1864, Assistant in Anatomy in 1868, Doctor in 1871, Prosector in 1872, Agrégé in 1875, Chief of Anatomical Works in 1878, Farabœuf, in 1887, succeeded Sappey in the chair of Anatomy of the Faculty. He was Member of the Academy of Medicine. He died at the age of 69 years, of intestinal obstruction by biliary calculi.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

IMPROVED HEALTH CONDITIONS IN MANILA—ETIOLOGY OF BERIBERI—INFANT MORTALITY—MOSQUITO CAMPAIGN IN MANILA—PHILIPPINE GENERAL HOSPITAL—PERSONALS.

MANILA, P. I., September 8, 1910.

THE annual report of the Bureau of Health for the fiscal year ended June 30, 1910, shows that there has been a marked fall in the mortality of the City of Manila for the year just closed. The average death rate for this city during the past five or six years has been approximately about 40 per thousand, while this year it was 34.93, or approximately 5 per thousand better than the average and by far the lowest death rate that has been recorded since American occupation. The cause of this improved state of affairs has not yet been announced, but it is informally understood that it was largely due to the installation of the new water system, the water from which was exclusively used in the city mains during the past year.

The death rate by nationalities was as follows: American, 12.93; Filipinos, 36.88; Spaniards, 15.65; other Europeans, 21.73; Chinese, 18.23; all others, 9.41.

The regular monthly meeting of the Manila Medical Society was held at 8:30 P.M., September 5, 1910, in the buildings in which the Philippine Medical School was formerly located. Captain E. D. Kilbourne of the United States Army, read an interesting paper, entitled "Preliminary Report of Multiple Neuritis of Fowls Due to Inanition." He exhibited a number of chickens which showed the clinical signs and symptoms of beriberi. This paper was another most important step in showing that the etiology of this disease is not of bacterial origin, but tends more and more to confirm the theory of insufficient or improper diet.

The remainder of the programme consisted of six papers upon the various phases of infant mortality. Nothing particularly new was elicited in this regard. In the discussion which followed, one of the speakers called attention to the few cases of so-called surgical tuberculosis, which were encountered here and suggested that this might be attributed to the very limited use of cow's milk and more especially that the use of other than canned and, therefore, sterile milk was almost unknown.

At the present time a mosquito campaign is being conducted in the resident section of Manila, the area covered being the four blocks which surround the new Philippine General Hospital on all sides. The work is being done by the Bureau of Health, under Dr. Banks, entomologist of the Bureau of Science. Dr. Banks is of the opinion that the mosquitoes that breed in the swamps in this neighborhood do not enter the dwelling houses of the residents of that section and that the large number of mosquitoes that are found in the houses are entirely of domestic origin. The campaign, therefore, consists of destroying only the breeding places which are found immediately around the premises; that is, septic vaults, rain barrels, tanks and all containers which are generally found to furnish breeding places for mosquitoes. If this campaign should prove successful, work upon a larger scale will be undertaken.

The construction work of the new Philippine General Hospital, particularly the interior finishing, was proceeding in the most discouragingly slow manner; the Governor-General during the latter part of July finally took the matter up and directed the Bureau of Public Works to finish the hospital in a period of thirty days, to such an extent at least that the patients at the Civil Hospital could be transferred to the new institution. This caused a tremendous activity and resulted directly in one pavilion of the hospital being made ready for occupancy on September 1st. The Bureau of Health had the Civil Hospital Division accordingly transferred to the Philippine General Hospital on September 2, and the old Civil Hospital, as such, has ceased to exist since that date. Many months must necessarily elapse before the new hospital can be opened to the general public. In the meantime the facilities which are available are superior to those which existed at the old Civil Hospital.

Dr. A. J. McLaughlin, Assistant Director of Health, has left upon a leave of absence in the United States.

Dr. P. K. Gilman, Assistant Professor of Surgery, Philippine Medical School, has gone to the United States upon leave of absence. Dr. John McDill is performing the duties of Dr. Gilman at the medical school, as well as his own.

Dr. Victor G. Heiser was designated physician to the Secretary of War during that official's visit of inspection to the various provinces.

Progress of Medical Science.

The Technique of Arthrotomy. A Report upon and Discussion of One Hundred and Ninety-eight Cases. C. F. Painter and A. F. Cornwall.
The Small Fibrous Prostate. A. L. Chute.
Analysis of Wound Infection in One Thousand Consecutive Clean Operative Cases. W. P. Graves.
The Comparative Histology of Femoral Bones. J. S. Foote.

The Technique of Arthrotomy.—C. F. Painter and A. F. Cornwall state that for many years surgeons have been loath to interfere with pathological or traumatic conditions located within the larger articulations, owing to the dangers of sepsis and the fear that permanent damage might be done to an articulation by the extent of the excision. With improvement in surgical technique the first of these fears has been largely eliminated. But fear of weakening the capsule of the joint is still a deterring factor in the minds of many surgeons. The authors lay stress upon the importance of postoperative treatment in all cases of arthrotomy, because the success of an operation is quite as much dependent upon the skill with which the joint is managed afterwards as it is upon the judgment which determined upon the operation and the skill which carried it to its completion. The first group of cases described are those of joint lipomata, including the "solitary lipomata," described by Koenig, the hypertrophied alar ligament fringes which are traumatic fibrolipomata, and the diffuse lipomata which usually represent merely the deposition of fat in the subsynovial tissues as a result of a fatty infiltration, occurring commonly in those given to adiposity.
